This article studies socially optimal allocations, from the point of view of a benevolent social planner, in environments characterized by fixed resources, endogenous fertility, and full information. Individuals in our environment are fully rational and altruistic toward their descendants. Our model allows for rich heterogeneity of abilities, preferences for children, and costs of raising children. We show that the planner's optimal allocations are efficient in the sense of [Goloso et al. \(2007\)](#). We also show that efficient allocation in the endogenous fertility case differs significantly from its exogenous fertility counterpart. In particular, optimal steady state population is proportional to the amount of fixed resources and the level of technology, while steady state individual consumption is independent of these variables, a sort of “Malthusian stagnation” result. Furthermore, optimal allocations exhibit inequality, differential fertility, random consumption, and a higher population density of poorer individuals even when the planner is fully equalitarian and faces no aggregate risk or frictions.

KEYWORDS. P-efficient, A-efficient, efficient population, endogenous fertility, stochastic abilities, inequality.

1. INTRODUCTION

There is growing interest in understanding the equilibrium and efficiency properties of economies characterized by endogenous fertility (e.g., [Goloso et al. \(2007\)](#), [Conde-Ruiz et al. \(2010\)](#), [Hosseini et al. \(2013\)](#), [Schoonbroodt and Tertilt \(2014\)](#), [Pérez-Nievas et al. \(2019\)](#)). As this literature makes clear, usual notions of efficiency may not apply when population is endogenous. This article contributes to this literature by studying in detail a case of major historical importance: the Malthusian case. In particular, we investigate the properties of socially optimal allocations, from the point of view of a benevolent social planner, in environments characterized by fixed resources and endogenous fertility.

We thank the anonymous referees for their very insightful comments. Xiyong Liu acknowledges support by the National Natural Science Foundation of China (Grant 71703117) and by Wuhan University (Grant 2017QN040).

Malthusian models have recently gained renewed interest as part of a larger literature seeking to provide a unified theory of economic growth, from prehistoric to modern times (e.g., Becker et al. (1990), Jones (1999), Galor and Weil (2000), Lucas (2002), Hansen and Prescott (2002), Doepke (2004)). The focus of this literature has been mostly positive rather than normative: to describe mechanisms for the stagnation of living standards even in the presence of technological progress. But the fundamental issue of efficiency in Malthusian economies, which is key to formulating policy recommendations and a better understanding of the extent to which the “Malthusian trap” could have been avoided, has received scarce attention. This paper seeks to fill this gap.

Our model economy is populated by a large number of finitely-lived fully rational individuals who are altruistic toward their descendants. Individuals are of different types, and a type determines characteristics such as labor skills, rate of time preference, and ability to raise children. Types are stochastic and determined at birth. We formulate the problem faced by a utilitarian social planner who cares about the welfare of all *potential* individuals, present and future, as in Golosov et al. (2007). We call the solutions to the planner’s problem optimal or efficient solutions.

The planner directly allocates consumption and number of children to individuals in all generations and states subject to aggregate resource constraints, promise-keeping constraints, population dynamics, and a fixed amount of natural resources. For short, we call “land” the fixed resource. The economy is closed: there is no capital accumulation or migration. Furthermore, there are no underlying frictions, such as private information or moral hazard, so that the focus is on first-best allocations. The rich structure of the model allows us to study questions of aggregate efficiency as well as distributional issues such as optimal inequality, social mobility, and social classes. Distributional considerations can be particularly challenging. Lucas (2002) shows that inequality is difficult to sustain as an equilibrium in Malthusian economies. In contrast, inequality and randomness arise naturally in our environment even when the planner weighs everyone in a given generation equally.¹

The main findings of this article are as follows. First, we show that the planner’s optimal allocations are P-efficient in the sense of Golosov et al. (2007). P-efficiency is a natural extension of Pareto efficiency for the case of endogenous population. It requires consideration of the utility of all potential individuals, not only born individuals. If the planner cares only about the initial living agents, the allocation is A-efficient, also in the sense of Golosov et al. (2007). We extend their results by introducing idiosyncratic shocks into the environment. Second, we find that stagnation of the Malthusian type is optimal. Specifically, optimal steady state consumption is independent of the amount of land and, under general conditions, the level of technology. As a result, land discoveries, such as those discussed by Malthus, would lead to more steady state population but no additional consumption. A similar prediction holds for technological progress as long as the production function is Cobb–Douglas or technological progress is land-augmenting—the type of progress that is more valuable because land is the limiting factor.

¹Consumption inequality arises naturally when Pareto weights are different and fertility is exogenous. What is new when fertility is endogenous is that (i) unequal Pareto weights do not automatically lead to unequal consumption and (ii) inequality can arise even if Pareto weights are equal and there are no frictions.

The source of the stagnation is a well known prediction of endogenous fertility models, according to which optimal consumption is proportional to the net costs of raising a child. For example, Becker and Barro find that “when people are more costly to produce, it is optimal to endow each person produced with a higher level of consumption. In effect, it pays to raise the ‘utilization rate’ (in the sense of a higher c) when costs of production of descendants are greater” (Becker and Barro (1988, p. 10)). We show that this link between optimal consumption and the net cost of raising children also holds for a benevolent planner and under more general conditions. The crux of the proof of stagnation is to show that neither land discoveries nor technological progress alters the steady state net cost of raising a child. In particular, the steady state marginal product of labor, which is needed to value both the parental time costs of children and children’s marginal output, is unaffected.

Third, we show that efficient allocations exhibit social classes. Only types with the highest rate of time preference have positive population shares and consumption shares in steady state. Furthermore, unlike the exogenous fertility case, it is generally not efficient to equalize consumption among types, even if the planners’ weights are identical, or to eliminate consumption risk. Efficient consumption is stochastic even in the absence of aggregate risk. These results are further implications of consumption being a function of the net cost of raising children. In an efficient allocation, poor individuals are those with the lowest net costs of raising children.²

Fourth, there is an inverse relationship between consumption and population size: the lower is the consumption of a type, the larger is its population share. It is efficient to let individuals with lower net costs of having children reproduce more, but it is also optimal to endow their children with lower consumption—one that is proportional to those net costs. As a result, there are more poor individuals than rich individuals in an efficient allocation. Furthermore, population differences among types are larger than their corresponding consumption differences. The factor controlling the differences depends positively on the elasticity of parental altruism to the number of children and depends negatively on the intergenerational elasticity of substitution.³

Fifth, fertility differs among types. Optimal fertility depends on parental types, but also on grandparental types. Given grandparent’s types, parents with particularly low costs of raising children would have more children than otherwise. Also, given parental types, grandparents with particularly high costs of raising children would have more grandchildren.

Sixth, steady state allocations and, in particular, the land–labor ratio, generally depend on initial the initial distribution of population and planner’s weights. This is unlike the neoclassical growth model, which features an efficient capital–labor ratio, also called the modified golden rule level of capital, that is independent of initial conditions and planner’s weights. Malthusian economies thus do not exhibit a clear separation between efficiency and distribution.

²Córdoba et al. (2014, 2016a,b) provide further characterizations of models with endogenous fertility and idiosyncratic risk.

³The intergenerational elasticity of substitution is analogous to the intertemporal elasticity of substitution, but applied to different generations rather than different periods. See Córdoba et al. (2019).

In light of these results, efficient allocations could rationalize three key aspects of Malthusian economies: (i) stagnation of individual consumption in the presence of technological progress and/or improvements in the availability of land; (ii) social classes, inequality, and widespread poverty; (iii) differential fertilities. These results could also help explain why the so-called Malthusian trap was so pervasive in pre-industrial societies. Even in the best-case scenario of an economy populated by loving rational parents and governed by an all-powerful benevolent rational planner, stagnation as well as social classes and differential fertility could still naturally arise. Our results also suggest that it is not irrational animal spirits, as suggested by Malthus, that ultimately explain the stagnation. Stagnation can be the result of a social optimal choice between the quality and quantity of life in the presence of limited natural resources.

Our paper is related to [Golosov et al. \(2007\)](#), who have shown that population is efficient in dynastic altruistic models of endogenous fertility of the Barro–Becker type with fixed land. They do not derive results about stagnation, the distribution of consumption and population, or differential fertility. [Lucas \(2002\)](#) studies market equilibrium in Malthusian economies populated by altruistic fully rational parents. His focus is on simple representative economies where fertility is equal across groups in the steady state. Lucas shows that stagnation arises under certain conditions and he discusses the difficulties in generating social classes. He can generate classes by assuming heterogeneity in the degree of time preference and binding saving constraints. As a result, the equilibrium with social classes is not efficient in his model. We can generate efficient social classes and differential fertility by allowing individuals to differ in their labor skills and costs of raising children.

Our paper also relates to [Dasgupta \(2005\)](#), who studies the optimal population in an endowment economy with fixed resources. He does not consider the cost of raising children and focuses on the special case of generation-relative utilitarianism. Our model is richer in production, altruism, and the technology of raising children. [Nerlove et al. \(1986\)](#) show that the population in the competitive equilibrium is efficient under two possible externalities: first, a larger population helps to provide more public goods such as national defense; second, a larger population reduces wages if there is a fixed amount of land. [Eckstein et al. \(1988\)](#) show that population can stabilize and nonsubsistence consumption arises in the equilibrium when fertility choices are endogenously introduced into a model with a fixed amount of land. Parents exhibit warm glow altruism, while our paper builds on pure altruism. [De la Croix \(2013\)](#) studies sustainable population by proposing non-cooperative bargaining between clans living on an island with limited resources. Children in his model act like an investment good for parents' old-age support.

The rest of the paper is organized as follows. Section 2 illustrates the issues and mechanisms at work using a simple decentralized Barro–Becker model with fixed resources. Section 3 sets up the planner's problem. Section 4 focuses on the deterministic representative agent version of the planner's problem and derives the main stagnation results. Section 5 considers deterministic heterogeneity and derives key results regarding the distribution of population and consumption across types, as well as the importance of initial conditions for the steady state. Section 6 studies the stochastic

case and derives the key result for differential fertility, consumption, and population. Section 7 decentralizes the planner’s problem by a competitive market. Section 8 concludes. Proofs of the symmetric case are provided in the [Appendix](#).

2. BARRO–BECKER MODEL WITH FIXED RESOURCES

This section uses a simple market economy to derive a set of baseline results that arise when fertility is endogenous and some factors of production are in fixed supply. The market economy helps motivate the paper and better understand the underlying mechanisms. The remainder of the paper then focuses on social planner solutions rather than market economies.

The economy is populated by Barro–Becker families who have access to a Cobb–Douglas technology in land and labor. Land should be understood more generally to include all resources in fixed supply.

Households The economy under consideration has a mass 1 of agents at time 0. Let $i \in [0, 1]$ denote an individual at the beginning of time, who is also the head of dynasty i . Individuals are initially endowed with $k_{i0} (\geq 0)$ units of land. The aggregate amount of land is fixed and given by $K = \int_0^1 k_{i0} di$. Time is discrete: $t = 0, 1, 2, \dots$.

Individuals live for two periods, one as children and one as adults. Children do not consume. A time $-t$ adult from dynasty i consumes c_{it} and has n_{it} children. The number of children is a continuous variable taking value in the interval $[0, \bar{n}]$. Let N_{it} be the size of dynasty i at time t and let $N_t = \int_0^1 N_{it} di$ be the total population at time t . The size is defined as $N_{it} = \prod_{s=0}^{t-1} n_{is}$ for $i \in [0, 1]$ and $t = 1, 2, \dots$. Let r_t be the rental rate of land and let q_t be its price. There are three costs of raising a child: a goods cost of η units per child, a time cost of λ units of labor per child, and the cost of providing k_{it+1} units of land per child, $q_t k_{it+1}$. Adults are subject to a budget constraint of the form

$$c_{it} + (\eta + q_t k_{it+1})n_{it} \leq w_t(1 - \lambda n_{it}) + (r_t + q_t)k_{it} \quad \text{for } t \geq 0,$$

where w_t is the wage rate and $1 - \lambda n_{it}$ is the labor supply.

Parents are assumed to be altruistic toward their children. In particular, the lifetime utility of a time $-t$ adult, U_{it} , takes the Barro–Becker form $U_{it} = c_{it}^\xi / \xi + \beta n_{it}^\psi U_{it+1}$, with $\xi \in (0, 1)$ and $\psi \in (\xi, 1)$. The dynastic problem can then be described as

$$\max_{\{c_{it}, k_{it+1}, N_{it+1}\}_{t=0}^\infty} \sum_{t=0}^\infty \beta^t N_{it}^\psi \frac{c_{it}^\xi}{\xi}$$

$$\text{subject to } c_{it} + (\eta + w_t \lambda + q_t k_{it+1}) \frac{N_{it+1}}{N_{it}} \leq w_t + (r_t + q_t)k_{it} \quad \text{for } t \geq 0,$$

given $k_{i0} > 0$.

Firms Firms produce using the Cobb–Douglas technology $F(K, L; A) = AK^\alpha L^{1-\alpha}$, which is constant returns in land, K , and labor, L . Parameter A refers to the state of technology. Firms hire labor and rent land in competitive labor markets.

Resource constraints The economy-wide resource constraints for land, labor, and production for $t \geq 0$ are

$$\int_0^1 N_{it}k_{it} di \leq K$$

$$L_t \leq \int_0^1 N_{it}(1 - \lambda n_{it}) di$$

$$\int_0^1 N_{it}c_{it} di + \eta \int_0^1 N_{it+1} di \leq F(K_t, L_t, A).$$

Definition of equilibrium Given an initial distribution of land and population $\{k_{i0}, N_{i0}\}_{i \in [0,1]}$, a competitive equilibrium comprises sequences of prices $\{q_t, r_t, w_t\}_{t=0}^\infty$ and allocations $\{c_{it}^*, n_{it}^*, k_{it+1}^*, N_{it+1}^*\}_{t=0, i \in [0,1]}^\infty$ such that (i) given prices, the allocations solve the dynastic problem, and (ii) land, labor, and goods markets clear.

Equilibrium Let $R_{t+1} \equiv (r_{t+1} + q_{t+1})/q_t$ be the gross return. The determination of land returns, consumption, fertility and wages for $t > 0$ are characterized as⁴

$$\left(\frac{c_{it}^*}{c_{it+1}^*}\right)^{\xi-1} = \beta(n_{it}^*)^{\psi-1}R_{t+1} = \beta(n_{it}^*)^{\psi-1}R_{t+1} \quad \text{for } t \geq 0 \text{ and } i \in [0, 1] \tag{1}$$

$$c_{it+1}^* = c_{t+1}^* = \frac{\xi}{\psi - \xi} [R_{t+1}(\eta + w_t\lambda) - w_{t+1}] \quad \text{for } t \geq 0 \text{ and } i \in [0, 1] \tag{2}$$

$$c_{it}^* = A\left(\frac{K}{L_t^*}\right)^\alpha (1 - \lambda n_{it}^*) - \eta n_{it}^* \quad \text{for } t \geq 0 \tag{3}$$

$$w_t^* = (1 - \alpha)A\left(\frac{K}{L_t^*}\right)^\alpha \quad \text{for } t \geq 0. \tag{4}$$

The first equation is an intergenerational version of the Euler equation with the special feature that the discount factor $\beta n_{it}^{\psi-1}$ depends on the number of children. The second equation is derived by combining first-order conditions for fertility and land holdings plus the budget constraint. It states that consumption is equal for all individuals after period 0 and proportional to the net future value costs of raising a child: $R_{t+1}(\eta + w_t\lambda) - w_{t+1}$. [Becker and Barro \(1988\)](#) first derived this result for a representative agent economy, while [Bosi et al. \(2011\)](#) extended it to a heterogeneous agent economy.

Equation (3) is the resource constraint in per capita terms, while (4) defines equilibrium wages. Plugging (2) into (1), it follows that fertility is the same for all individuals in a generation; that is, $n_{it} = n_t$ for all $t > 0$. Thus, initial differences in land holding among individuals do not persist through differences in consumption or fertility of their descendants. Instead, they persist through differences in population sizes N_{it}^* . This is in contrast to the exogenous population version of the model in which any initial inequality in land holdings translates into persistent consumption differences.⁵

⁴Section 7 provides the solution to a generalized version of this model.

⁵If $n = 1$ is imposed, then the equilibrium satisfies $k_{it} = k_{i0}$, $c_{it} = c_i = w(1 - \lambda) + rk_{i0} - \eta$, $w = F_L(K, (1 - \lambda)N; A)$, and $r = F_K(K, (1 - \lambda)N; A)$ for all $t \geq 0$ where F_L and F_K define the marginal product of labor and capital, respectively.

Steady state For concreteness, we now focus on steady state solutions. A steady state population requires fertility to be 1. In that case, (1) reduces to the standard gross return determination $\beta R^* = 1$, while using (3), equalities (2) and (4) can be written as the system of two equations in two unknowns:

$$c^* = \frac{\xi}{\psi - \xi} [\eta/\beta + (\lambda/\beta - 1)w^*] \tag{5}$$

$$w^* = \frac{1 - \alpha}{1 - \lambda} (c^* + \eta). \tag{6}$$

Surprisingly, neither A nor K appears in this system. Consequently, steady state consumption and wages are independent of the technological level, A , or the fixed amount of resources, K , when fertility is endogenous. In contrast, both consumption and wages increase with A and K when fertility is exogenous (see footnote 5).

Substituting (6) into (5) and solving for c^* results in

$$c^* = c(\eta, \lambda, \beta, \psi, \xi) = \frac{1/\beta - (1 - \lambda/\beta) \frac{1 - \alpha}{1 - \lambda}}{\frac{\psi - \xi}{\xi} + (1 - \lambda/\beta) \frac{1 - \alpha}{1 - \lambda}} \eta.$$

According to this equation, consumption is a positive function of the goods and time costs of raising children. Use (4) and (6) to find the solution for population:

$$N^* = N(A, K, \eta, \lambda, \beta, \psi, \xi) = \left[\frac{(1 - \lambda)^{1-\alpha} A}{c(\eta, \lambda, \beta, \psi, \xi) + \eta} \right]^{1/\alpha} K.$$

Steady state population responds positively to technology and resource availability. and responds negatively to consumption and its underlying determinants.

To conclude this section, we highlight three qualitative differences between the endogenous and the exogenous fertility versions of the model. First, steady state individual consumption is unaffected by technological progress or the discovery of new resources when fertility is endogenous, while it fully responds when fertility is exogenous. Second, steady state population fully responds to technological progress or discoveries of new resources when fertility is endogenous, while, by assumption, population is unaffected in the exogenous fertility case. Third, any initial inequality in land holdings vanishes when population is endogenous. while it perpetuates when population is exogenous. We now investigate the extent to which the predictions of the canonical model of this section hold more generally, particularly from a planner’s perspective.

3. EFFICIENT ALLOCATIONS

This section considers social optima for more general specifications of preferences, technologies, and rich heterogeneity in earning abilities, ability to raise children, and altruism toward children, as well as stochastic intergenerational transmission of abilities and altruism. We focus on planner’s solutions rather than market equilibria for at least two reasons. First, characterizing social optima allocations is of interest on its own. One

may suspect, for example, that some of the baseline results, such as consumption not responding to technological progress, may be due to some type of market failure. Second, planner's solutions are often simpler to obtain than market solutions, particularly when fertility is endogenous and parents are fully altruistic. In this case, Barro–Becker preferences provide a tractable benchmark, but little is known for more general altruistic preferences.

We find that the first two features of the equilibrium solution are generally also properties of the planner's solution: consumption remains unresponsive to discoveries of new natural resources or to technological progress in the Cobb–Douglas case, or to land-augmenting technological progress for a more general formulation of the production function. Long-run equality, however, is not a robust feature. We are able to generate long-run inequality and social mobility in the stochastic version of the model. In this regard, our approach is very different from that of Lucas (2002). He is able to generate two social classes, with no possibility of social mobility, by assuming that the rate of time discount is a non-monotonic function of consumption. This nonstandard feature is violated, for example, by the Barro–Becker model. We instead rely on stochastic types that result, even in the full information case, in inequality and social mobility.

3.1 Preliminaries

Consider an infinite horizon stochastic economy with fixed resources. Time is discrete: $t = 0, 1, 2, \dots$. Individuals live for two periods—one as a child and one as an adult—and are altruistic toward their children. Children do not consume. The economy is initially populated by a continuum of agents with identity $i_0 \in P_0 \equiv [0, 1]$. Each person can give birth to a maximum of \bar{n} children. The potential population at time $t \geq 0$ is defined as $P_t \equiv P_0 \times [0, \bar{n}]^t$. A potential individual in period t , i.e., a person who could be born in period t , is identified by $i^t = [i_0, i_1, \dots, i_t] \in P_t$.

At time t , each potential agent i^t has a type $\omega_t(i_t) \in \Omega \equiv \{\omega_1, \omega_2, \dots, \omega_K\}$. A type determines an agent's labor skills, rate of time preference, and ability to raise children if born. Specifically, assume that labor supply $l(\omega)$, parental time discounting $\beta(\omega)$, and the goods and time costs of raising a child, $\eta(\omega)$ and $\lambda(\omega)$, are functions of an individual's type. Let $\pi(\omega', \omega)$ denote the probability that a type ω parent has type ω' child and assume $\pi(\omega', \omega) > 0$ for all $(\omega', \omega) \in \Omega$. Let Ω_0 be the set of types with positive mass at $t = 0$ and let $\bar{N}_0(\omega^0) = N_0(\omega_0)$ be the initial mass of population of type $\omega_0 \in \Omega_0$. Define the set of possible types at time t recursively as $\Omega_t \equiv \Omega_{t-1} \times \Omega$. Associated with each potential agent i^t , there is a history of shocks of that agent's ancestors, including $\omega^t(i^t) = [\omega_0(i_0), \omega_1(i_1), \dots, \omega_t(i_t)] \in \Omega_t$. Assuming that a law of large numbers holds, the potential population with family history $\omega^{t+1} \in \Omega_{t+1}$ is given by

$$\bar{N}_{t+1}(\omega^{t+1}) = \pi(\omega_{t+1}, \omega_t) \bar{n} \bar{N}_t(\omega^t) \quad \text{for } t > 0,$$

where \bar{n} is the maximum number of children possible. Notice that the number of potential individuals is completely exogenous. Moreover, the assumption that $\pi(\omega', \omega) > 0$ guarantees that $\bar{N}_{t+1}(\omega^{t+1})$ is strictly positive for all $\omega^{t+1} \in \Omega_{t+1}$.

A fertility plan, denoted by $\widehat{\mathbf{n}} = \{\{n_t(i^t, \omega^t)\}_{\omega^t \in \Omega_t}^{i^t \in P_t}\}_{t=0}^\infty$, is a description of the number of children born to potential agent i^t for each possible history of shocks ω^t . Thus, $0 \leq n_t(i^t, \omega^t) \leq \bar{n}$ for all $i^t \in P_t$ and $\omega^t \in \Omega_t$. Each fertility plan implicitly defines a subset $I_t(n) \subset P_t$ of individuals actually born under the plan n .⁶ An allocation is a fertility plan \widehat{n} and a consumption plan $\widehat{\mathbf{c}} = \{\{c_t(i^t, \omega^t)\}_{\omega^t \in \Omega_t}^{i^t \in I_t(n)}\}_{t=0}^\infty$. A *symmetric* allocation is an allocation such that for all $i^t \in I_t(n)$, $\omega^t \in \Omega_t$, and $t \geq 0$, $c_t(i^t, \omega^t) = c_t(\omega^t)$ and $n_t(i^t, \omega^t) = n_t(\omega^t)$. A symmetric allocation thus provides the same consumption and fertility to born individuals with the same history regardless of their identity i^t . For simplicity, we consider only symmetric allocations from now on, as in Phelan and Rustichini (2018). Let $(\mathbf{c}, \mathbf{n}) = \{\{c_t(\omega^t), n_t(\omega^t)\}_{\omega^t \in \Omega_t}\}_{t=0}^\infty$ denote symmetric allocations for born individuals.⁷

3.2 Resource constraints

The production technology is described by the constant returns to scale function $F(K, L; A)$ with respect to K and L , where K is a fixed amount of land, L is labor, and A is a technological parameter. Suppose F is constant returns to scale in K and L . Let $\alpha(\frac{K}{L}, A) \equiv F_K(K, L; A)K/F(K, L; A)$ denote the land share of output. Aggregate labor supply satisfies

$$L_t = \sum_{\omega^t \in \Omega_t} N_t(\omega^t)l(\omega_t)[1 - \lambda_t(\omega_t)n_t(\omega^t)] \quad \text{for } t \geq 0, \tag{7}$$

where $N_t(\omega^t)$ is the *born* population, or just population, with family history ω^t , $l(\omega_t)$ is the labor supply of an individual of type ω_t , $\lambda_t(\omega_t)$ is the cost of raising a child, and $l(\omega_t)[1 - \lambda_t(\omega_t)n_t(\omega^t)]$ is the effective labor supply. Population evolves according to

$$N_{t+1}(\omega^{t+1}) = N_t(\omega^t)n_t(\omega^t)\pi(\omega_{t+1}, \omega_t) \quad \text{for } t \geq 0 \text{ and } \omega^{t+1} \in \Omega_{t+1}, \tag{8}$$

given $N_0(\omega^0)$ for $\omega^0 = \omega_0 \in \Omega_0$. Let $N_t \equiv \sum_{\omega^t} N_t(\omega^t)$ be the total population at time t . The aggregate resource constraint at time t is then described by

$$F(K, L_t; A) = \sum_{\omega^t \in \Omega_t} N_t(\omega^t)[c_t(\omega^t) + \eta(\omega_t)n_t(\omega^t)] \quad \text{for } t \geq 0. \tag{9}$$

DEFINITION 1. A (symmetric) allocation (\mathbf{n}, \mathbf{c}) is feasible if it satisfies (7), (8), and (9) given $[N_0(\omega)]_{\omega \in \Omega_0}$.

⁶More precisely, let the set $I_t(n)$ be defined recursively by $i_0 \in I_0(n)$ for $i_0 \in P_0$. Then $(i_0, i_1) \in I_1(n)$ for $i_0 \in P_0$ and $\omega_0 \in \Omega_0$ if and only if $0 \leq i_1 \leq n_0(i_0, \omega_0)$, and so forth. In particular, $i^{t+1} \in I_{t+1}(n)$ if $0 \leq i_{t+1} \leq n_t(i^t, \omega^t)$ for $i^t \in I_t(n)$ and $\omega^t \in \Omega_t$.

⁷We can show that in a full model, one that does not impose symmetry, optimal allocations are symmetric if the planner’s weights are symmetric, parents care about all their born children equally, and optimal solutions are interior. Proof is available upon request.

3.3 Individual welfare

Parents are assumed to be altruistic toward their children. The lifetime utility of an individual born at time $t \geq 0$ and history ω^t is of the expected-utility form

$$U_t(\omega^t) = u(c_t(\omega^t)) + \beta(\omega_t)\Phi(n_t(\omega^t))E[U_{t+1}(\omega^{t+1})|\omega^t] + \beta(\omega_t)(\Phi(\bar{n}) - \Phi(n_t(\omega^t)))\underline{U}, \tag{10}$$

where $u(\cdot)$ is the utility flow from consumption, $\beta(\omega)$ is a time discounting factor, $\Phi(n)$ is the weight that a parent attaches to the welfare of her n born children, $\Phi(\bar{n}) - \Phi(n)$ is the weight attached to the unborn children, $E[U_{t+1}(\omega^{t+1})|\omega^t]$ is the expected utility of a born child conditional on parental history, and \underline{U} is the utility of an unborn child.⁸ Function u satisfies $u' > 0$ and $u'' < 0$.

Equation (10) describes parents as social planners at the family level. This is particularly clear in the special case $\Phi(n) = n$. The more general function $\Phi(\cdot)$ allows for diminishing utility from children. While $\Phi(n)$ is the total weight of the n born children, $\Phi_n(n)$ is the marginal weight assigned to the n child, where $n \in [0, \bar{n}]$. We assume $\Phi_n(n) > 0$ and $\Phi_{nn}(n) \leq 0$ so that parents are altruistic toward each child and marginal altruism is nonincreasing. These preferences are discussed by Córdoba et al. (2011), where they show that (10) satisfies a fundamental axiom of altruism. Specifically, parental utility increases with the number of born children if and only if children are better off born than unborn in expected value, that is, $E[U_{t+1}(\omega^{t+1})|\omega^t] > \underline{U}$. Let $\bar{U}_t(\omega^t)$ be the utility of a potential agent with history ω^t . In particular, $\bar{U}_t(\omega^t) = U_t(\omega^t)$ if the individual is born and $U_t(\omega^t) = \underline{U}$ if unborn.

Let $\xi(c) \equiv u'(c)c/u(c)$ be the elasticity of the utility flow and let $\psi(n) \equiv \Phi'(n)n/\Phi(n)$ be the elasticity of the altruistic function. Barro–Becker preferences are a special case obtained when $u(c) = c^\xi/\xi$, $\beta(\omega) = \beta$, $\Phi(n) = n^\psi$, $\underline{U} = 0$, $\xi \in (0, 1)$, and $\psi \in (\xi, 1)$.

3.4 Social welfare

We consider a social planner who cares about the welfare of all *potential* individuals. In particular, social welfare takes the utilitarian form

$$SW_1 = \sum_{t=0}^{\infty} \sum_{\omega^t \in \Omega_t} \varphi_t(\omega^t)\bar{N}_t(\omega^t)\bar{U}_t(\omega^t), \tag{11}$$

where $\varphi_t(\omega^t)$ is the weight that the planner puts on an individual with history ω^t . It could vary among different types and it includes time discounting by the planner. When all potential individuals of the same generation are equally weighted, the weight represents only time discounting, e.g., $\varphi_t(\omega^t) = \delta^t$. Here we focus on the symmetric weight of the planner on people of the same history ω^t . Notice that the planner faces no uncertainty because a law of large numbers is assumed so that all risk is idiosyncratic.

⁸The population ethics literature refers to \underline{U} as the “neutral” utility level, a level above which a life is worth living (Blackorby and Donaldson (1984, p. 21)).

Alternatively, we consider a social planner who cares only about the initial generation as well as future generations, but only to the extent that the initial generation does. In that case, the planner’s objective function becomes

$$SW_2 = \sum_{\omega \in \Omega_0} \varphi_0(\omega) N_0(\omega) U_0(\omega). \tag{12}$$

Different from SW_2 , SW_1 refers to a planner who is more patient than individuals, as in [Farhi and Werning \(2007\)](#). We assume throughout that parameter values are such that social welfare is bounded.

The following assumption bounds the extent to which the planner cares about future generations.

ASSUMPTION 1. We have $\lim_{t \rightarrow \infty} \frac{\varphi_t(\omega^t)}{\prod_{j=0}^{t-1} \beta(\omega_j)} = 0$ for all $\omega^t \in \Omega_t$.

The role of Assumption 1 is tractability. The assumption is not particularly restrictive because it still allows for the planner to care about future generations more than parents do. To see this, consider for a moment the case $\varphi_t(\omega^t) = \delta^t$, $\beta(\omega) = \beta$. In that case, Assumption 1 is satisfied when $\delta < \beta$. In the [Appendix](#), we analyze the case $\delta \geq \beta$, which is less tractable, but we can still prove that Malthusian stagnation holds in that case (see [Appendix A.2](#)).

DEFINITION 2 (Planner’s problem). Given an initial distribution of population $\{N_0(\omega)\}_{\omega \in \Omega}$, the planner’s problem is to choose a feasible allocation (\mathbf{n}, \mathbf{c}) that maximizes social welfare defined by either (11) or (12). An efficient allocation is one that maximizes social welfare.

The following definitions of P- and A-efficiency extend those of [Goloso et al. \(2007\)](#) and [Pérez-Nievas et al. \(2019\)](#) to our stochastic environment.⁹

DEFINITION 3. A feasible allocation $(\mathbf{n}^*, \mathbf{c}^*)$ is P-efficient if there is no other feasible allocation $(\hat{\mathbf{n}}, \hat{\mathbf{c}})$ such that (i) $\bar{U}_t(\omega^t) \geq \bar{U}_t^*(\omega^t)$ for all $\omega^t \in \Omega_t$, and $t \geq 0$ where $\bar{U}_t^*(\omega^t)$ and $\bar{U}_t(\omega^t)$ are the utilities of the individual with history ω^t under the allocations (n^*, c^*) and (\hat{n}, \hat{c}) , respectively, and (ii) $\bar{U}_t(\omega^t) > \bar{U}_t^*(\omega^t)$ for at least one $\omega^t \in \Omega_t$.

DEFINITION 4. A feasible allocation (n^*, c^*) is A-efficient if there is no other feasible allocation (\hat{n}, \hat{c}) such that (i) $\bar{U}_0(\omega_0) \geq \bar{U}_0^*(\omega_0)$ for all $\omega_0 \in \Omega_0$, where $\bar{U}_0^*(\omega_0)$ and $\bar{U}_0(\omega_0)$

⁹[Goloso et al. \(2007\)](#) define A- and P-efficiency for deterministic environments, but do not restrict allocations to be symmetric, as we do. [Schoonbroodt and Tertilt \(2014\)](#) consider the possibility of asymmetric allocations in a related deterministic market environment. They find that symmetric allocations are A- and P-efficient absent market failures (see their Proposition 1). Their results support our focus on symmetric allocations since our environment is frictionless. Asymmetric allocations could improve upon symmetric allocations when market failures bind, as they show. See Footnote 7 above for further discussion of the asymmetric case.

are the utilities of the initial generation of type ω_0 under the allocation $(\mathbf{n}^*, \mathbf{c}^*)$ and $(\hat{\mathbf{n}}, \hat{\mathbf{c}})$, respectively, and (ii) $\bar{U}_0(\omega_0) > \bar{U}_0^*(\omega_0)$ for at least one $\omega_0 \in \Omega_0$.¹⁰

Next, we show that a solution to the planner’s problem SW₁ is P-efficient under mild conditions. Similarly, a solution to the planner’s problem SW₂ is both P- and A-efficient.

PROPOSITION 1. (i) A solution to the planner’s problem SW₁ is P-efficient if $\varphi_t(\omega^t) \geq 0$ for all $\omega^t \in \Omega_t, t > 0$. (ii) A solution to the planner’s problem SW₂ is P-efficient if the solution is unique.

PROPOSITION 2. A solution to the planner’s problem SW₂ is A-efficient if $\varphi_0(\omega_0) > 0$ for all $\omega_0 \in \Omega_0$ or if the solution is unique.

Proposition 1 and its proof are analogous to Results 1 and 2 in Golosov et al. (2007), but our setup is different in that it allows for randomness and restricts feasible allocations to be symmetric. Under SW₁, the proposition does not require uniqueness, as in their Result 1, because the weights of all potential individuals are assumed to be strictly positive. Similarly to their Result 2, using SW₂ requires us to assume uniqueness given that planner’s weights of future generations are assumed to be zero.

We now proceed to further characterize the optimal solution. We assume parameter values are such that the solution is unique and interior.¹¹ Furthermore, we normalize the utility of the unborn to be zero: $\underline{U} = 0$. In that case, social welfare reduces to $\sum_{t=0} \sum_{\omega^t \in \Omega_t} \varphi_t(\omega^t) N_t(\omega^t) U_t(\omega^t)$. Let $\kappa_t, \gamma_{t+1}(\omega^{t+1}), \mu_t$, and $\theta_t(\omega^t) N_t(\omega^t)$ be nonnegative Lagrangian multipliers associated to restrictions (7), (8), (9), and (10). The first-order conditions with respect to $\{U_t(\omega^t), N_{t+1}(\omega^{t+1}), n_t(\omega^t), c_t(\omega^t), L_t\}_{\omega^t \in \Omega_t, t \geq 0}$ are¹²

$$\theta_0(\omega_0) = \varphi_0(\omega_0) \tag{13}$$

$$\begin{aligned} &\theta_{t+1}(\omega^{t+1}) N_{t+1}(\omega^{t+1}) \\ &= \theta_t(\omega^t) \beta(\omega_t) \Phi(n_t(\omega^t)) N_t(\omega^t) \pi(\omega_{t+1}, \omega_t) + \varphi_{t+1}(\omega^{t+1}) N_{t+1}(\omega^{t+1}) \end{aligned} \tag{14}$$

$$\begin{aligned} &\varphi_{t+1}(\omega^{t+1}) U_{t+1}(\omega^{t+1}) + \gamma_{t+1}(\omega^{t+1}) + \kappa_{t+1} l(\omega_{t+1}) [1 - \lambda_{t+1}(\omega_{t+1}) n_{t+1}(\omega^{t+1})] \\ &= \mu_{t+1} [c_{t+1}(\omega^{t+1}) + \eta(\omega_{t+1}) n_{t+1}(\omega^{t+1})] \\ &\quad + n_{t+1}(\omega^{t+1}) \sum_{\omega^{t+2} | \omega^{t+1}} \gamma_{t+2}(\omega^{t+2}) \pi(\omega^{t+2}, \omega^{t+1}) \end{aligned} \tag{15}$$

¹⁰Golosov et al. (2007) define A-efficiency more generally by comparing the welfare profiles of agents alive in alternative allocations. They show that A-efficiency includes more than dynastic maximization. But Pérez-Nievas et al. (2019), Abstract show that “[i]f potential agents are identified by the dates in which they may be born, then A-efficiency reduces to dynastic maximization.” Golosov et al. (2007) assume instead that potential agents are identified by their position in their sibling’s birth order. Our definition of A-efficiency therefore assumes that potential agents are identified by the birth date criterion.

¹¹For example, the Barro–Becker formulation possesses an interior solution under certain parameter restrictions.

¹²To avoid cumbersome notation, we do not introduce new notation to identify optimal allocations. Allocations should be regarded as optimal from now on. The Lagrangian is written in the proof of Proposition 3.

$$\begin{aligned} &\theta_t(\omega^t)\beta(\omega_t)\Phi_n(n_t(\omega^t))E_tU_{t+1}(\omega^{t+1}) \\ &= \mu_t\eta(\omega_t) + \kappa_t l(\omega_t)\lambda_t(\omega_t) + \sum_{\omega^{t+1}|\omega^t} \gamma_{t+1}(\omega^{t+1})\pi(\omega^{t+1}, \omega^t) \end{aligned} \tag{16}$$

$$\theta_t(\omega^t)u'(c_t(\omega^t)) = \mu_t \tag{17}$$

$$\mu_t F_{L_t} = \kappa_t, \tag{18}$$

where

$$F_{L,t} \equiv \left(1 - \alpha\left(\frac{K}{L_t}, A\right)\right) \frac{F(K, L_t; A)}{L_t}. \tag{19}$$

This system of equations together with (7), (8), (9), (10), and proper transversality conditions fully describe optimal allocations. Equation (13) states that the social value of providing additional utility to an individual of type ω_0 is just the Pareto weight of that individual, $\varphi_0(\omega_0)$. Equation (14) then allows us to trace the evolution of $\theta_t(\omega^t)$, which is, in fact, the effective Pareto weight of an individual in state ω^t . The left-hand side of the equation is the marginal cost of providing utility $U_{t+1}(\omega^{t+1})$, while the right-hand side is its marginal benefit. It includes a benefit to the altruistic parents plus a direct benefit to the planner, $\varphi_{t+1}(\omega^{t+1})$.

Equation (15) equates marginal benefits to marginal costs of more population. To better understand this expression, suppose for a moment that population is not constrained by (8), for example, because the planner has access to an infinite pool of immigrants. In that case, $\gamma_{t+1}(\omega^{t+1}) = 0$ for all t and ω^{t+1} . The marginal benefit of an additional individual of type ω^{t+1} includes her direct effect in social welfare $\varphi_{t+1}(\omega^{t+1})U_{t+1}(\omega^{t+1})$ plus her effect in the labor supply $\kappa_{t+1}l(\omega_{t+1})[1 - \lambda_{t+1}(\omega_{t+1}) \times n_{t+1}(\omega^{t+1})]$, while the marginal cost includes the costs of providing consumption and children to the individual $\mu_{t+1}[c_{t+1}(\omega^{t+1}) + \eta(\omega_{t+1})n_{t+1}(\omega^{t+1})]$. Adding restriction (8) makes the individual more valuable in the amount $\gamma_{t+1}(\omega^{t+1})$ because it relaxes the population constraint at $t + 1$, but also increases marginal cost because the planner needs to endow the individual with children at $t + 2$.

The condition for optimal fertility is (16). The marginal benefit of a child for an altruistic parent with history ω^t is the expected utility of the child E_tU_{t+1} times the weight that the parent attaches to the child $\beta(\omega_t)\Phi_n(n_t(\omega^t))$. The marginal benefit for the planner is this amount times $\theta_t(\omega^t)$, expressed in consumption goods. The corresponding marginal cost of the child for the planner includes good costs $\mu_t\eta(\omega_t)$, time costs $\kappa_t l(\omega_t)\lambda_t(\omega_t)$, and the expected shadow costs of a descendant $\sum_{\omega^{t+1}|\omega^t} \gamma_{t+1}(\omega^{t+1})\pi(\omega_{t+1}, \omega_t)$.

To characterize the solution of this system, we focus primarily on the steady state and proceed in three steps.¹³ First, we characterize the deterministic case with only one type (Section 4), then the case with multiple but deterministic types (Section 5), and finally the stationary solution with stochastic types. We show that Malthusian stagnation generally arises when technological progress is of the land-augmenting type, meaning

¹³Appendix A.2.2 provides necessary and sufficient conditions for stability for the deterministic case with $\delta = 0$. As shown below, the steady state of the model with $\delta < \beta$ is similar to that of $\delta = 0$.

that steady state optimal consumption and fertility choices are independent of K and A . We also characterize the optimal composition of population, the potential dependence of the steady state land–labor ratio on initial conditions, and fertility differentials among types.

4. DETERMINISTIC CASE WITH ONE TYPE

This section considers the representative agent case with only one type. Assume $\varphi_t(\omega) = \varphi_t$ for all $\omega \in \Omega$. Let $n(\omega) = n$, $\lambda(\omega) = \lambda$, $\eta(\omega) = \eta$, $\beta(\omega) = \beta$, and $l(\omega) = 1$ for simplicity. In this case, the resource constraint (9) reduces to

$$F\left(\frac{K}{N_t}, 1 - \lambda n_t; A\right) = c_t + \eta n_t. \tag{20}$$

Moreover, using (17), (18), and (20), (13)–(16) simplify to

$$\begin{aligned} \theta_0 &= \varphi_0 \\ \varphi_{t+1} + \theta_t \beta \frac{\Phi(n_t)}{n_t} &= \theta_{t+1} \end{aligned} \tag{21}$$

$$\varphi_{t+1} U_{t+1} + \gamma_{t+1} = \mu_{t+1} F_{K,t+1} \frac{K}{N_{t+1}} + n_{t+1} \gamma_{t+2} \tag{22}$$

$$\beta \Phi'(n_t) \frac{U_{t+1}}{u'(c_t)} = \eta + F_{L,t} \lambda + \frac{\gamma_{t+1}}{\gamma_t} \frac{\gamma_t}{\mu_t}. \tag{23}$$

Equation (22) is obtained from (15) after using (18), (20), and the constant returns to scale assumption. Equation (23) is obtained from (16), (17), and (18). The following proposition provides a sharp characterization of consumption for all periods, except period 0, for the special case $\Phi(n) = n^\psi$.

PROPOSITION 3. *Assume $\Phi(n) = n^\psi$, $0 < \psi < 1$, and let $a_m \equiv \varphi_m \beta^{-m} N_m^{1-\psi}$ if $\varphi_m > 0$ or $a_m = 0$ otherwise. Then efficient consumption satisfies*

$$c_{t+1} = \frac{\xi(c_{t+1})}{\psi - \xi(c_{t+1})} \left[\frac{\mu_t}{\mu_{t+1}} (\eta + F_{L,t} \lambda) - F_{L,t+1} - \frac{a_{t+1}}{\sum_{m=0}^{t+1} a_m} \frac{U_{t+1}}{u'(c_{t+1})} (1 - \psi) \right]. \tag{24}$$

This expression is similar, but generalizes (2). The term $(\mu_t / \mu_{t+1})(\eta + F_{L,t} \lambda) - F_{L,t+1}$ is the net future cost of raising a child from the planner’s perspective. The main difference is the last term in the brackets. This term equals zero when $t \rightarrow \infty$ since $\lim_{t \rightarrow \infty} \varphi_t \beta^{-t} = 0$. In essence, when planner’s preferences differ from those of the individuals, because $\varphi_t > 0$ for $t > 0$, then consumption is adjusted downward to free resources so as to expand population. But those adjustments are temporary given that the limit of $\varphi_t \beta^{-t}$ goes to zero is assumed. In the limit, consumption becomes a sole function of the net cost of raising a child.

4.1 Steady state

Consider the steady state situation in which N , c , U , and L are constant and $n = 1$. The following result holds for general functions F , u , and Φ .

LEMMA 1. *Steady state consumption satisfies*

$$c = \frac{\xi(c)}{\psi(1) - \xi(c)} [\eta/\beta + (\lambda/\beta - 1)F_L]. \tag{25}$$

This expression generalizes (5). It shows that consumption is a function of the net costs of raising a child: $(\eta + \lambda F_L)/\beta - F_L$. The parametric restriction $\psi(1) > \xi(c)$ is needed for consumption to be positive. An implication of this result is that immiseration and the repugnant conclusion of $c = 0$ and $N = \infty$ is not optimal unless the net cost of children is zero. Although infinite population is a possibility in P-efficient allocations, this is not the case in our model. Population can only be gradually built up from fertility over time. An arbitrarily large population is avoided by introducing enough time discounting. This is similar to having bounded solutions in the Ramsey model. Besides the time discounting, models with endogenous fertility also require parameters such that children are a net financial costs to keep fertility interior and prevent population from going to infinity.

The resource constraint (20) can be written as

$$F_L = \frac{1 - \alpha(k; A)}{1 - \lambda} (c + \eta), \tag{26}$$

where $k = K/L$. Equations (25) and (26) form a system of two equations in three unknowns: c , F_L and α . In the case of a Cobb–Douglas production function, the land share α is a parameter and these two equations can be used to solve for consumption c and the marginal product of labor F_L independently of K and A , as in Section 2.

In the more general case, (19) is needed to close the system. It can be written as

$$F_L = (1 - \alpha(k; A))F(k, 1; A). \tag{27}$$

Equations (25), (26), and (27) form a system of three equations in three unknowns: c , F_L , and k . Since K does not appear in this system the solutions for c , F_L , and k are independent of the amount of land for any constant returns to scale production function. Given k , steady state population can be solved as $N = K/((1 - \lambda)k)$.

Finally, if A is a land-augmenting parameter, then the land share is a function of $\hat{k} = AK/L$. In that case, (26) and (27) can be written as $F_L = [(1 - \alpha(\hat{k}))/ (1 - \lambda)](c + \eta)$ and $F_L = (1 - \alpha(\hat{k}))F(\hat{k}, 1)$, and the solutions for c , F_L , and \hat{k} are independent of A . Given \hat{k} , steady state population is given by $N = AK/((1 - \lambda)\hat{k})$. The following proposition summarizes these findings.

PROPOSITION 4. *In steady state, efficient consumption is independent of the amount of land, while efficient population increases proportionally with the amount of land. Furthermore, if technological progress is land-augmenting, then efficient consumption is independent of the level of technology, while efficient population increases proportionally with the level of technology.*

5. DETERMINISTIC CASE WITH MULTIPLE TYPES

Consider now the case of multiple deterministic types. Specifically, suppose $\omega^t = [\omega, \omega, \omega, \dots]$ or just $\omega^t = \omega$ for short. We assume in this section $\varphi_{t+1}(\omega) = 0$ for all $t \geq 0$ and $\omega \in \Omega$. This restriction is without much loss of generality, since similar steady state results are obtained as long as $\lim_{t \rightarrow \infty} \varphi_t(\omega)\beta^{-t} = 0$ for all $\omega \in \Omega$, as shown in the previous section. For tractability, we also restrict altruism to be of the Barro–Becker form $\Phi(n) = n^\psi$, but allow general functional forms for u and F .

We show the following results in this section. First, if $\beta(\omega)$ is different for different types, then their population sizes grow at different rates and in steady state, only the most patient groups—those with highest $\beta(\omega)$ —survive. This result implies that efficient social classes cannot be sustained by persistent differences in rates of time preference. Lucas (2002) is able to generate social classes using such a mechanism in a competitive equilibrium with savings constraints, which suggests that social classes are not efficient, in the first best sense, in his model.

As an alternative to Lucas (2002), we are able to generate multiple social classes using a more standard mechanism based on heterogeneity in labor skills $l(\omega)$ and the cost of raising children $\eta(\omega)$ and $\lambda(\omega)$. This is the second main result of the section. Efficiency requires providing more consumption to individuals with higher costs of raising them. Consumption also increases with labor ability $l(\omega)$, but only if $\lambda(\omega) > \beta(\omega)$, that is, only if the time costs of raising children are sufficiently high. Otherwise, the efficient allocation involves the high skilled having lower consumption.

Third, we show that the relative population size of a type is inversely related to its relative consumption. Therefore, the population of the poor is larger than the population of the middle class and so on. The planner thus faces a quantity–quality trade-off: she can deliver a certain level of welfare by allocating number of children and/or consumption. If children are particularly costly to raise for a certain group, then the planner optimally delivers welfare more through consumption than through number of children and vice versa.

Fourth, in the deterministic steady state of this section, all types have one child and, therefore, steady state welfare differences among types arise only from differences in consumption. As a result, types with lower consumption are worse off than types with higher consumption. All benefits from a larger population accrue only to early members of the dynasty at the expense of later members.

5.1 Dynamics

The following lemma characterizes the evolution of efficient population sizes of different types over time.

LEMMA 2. *Let $(\omega, \omega') \in \Omega$. Efficient population sizes satisfy*

$$\frac{N_t(\omega)}{N_t(\omega')} = \left(\frac{\beta(\omega)}{\beta(\omega')} \right)^{\frac{1}{1-\psi}} \frac{N_0(\omega)}{N_0(\omega')} \left[\frac{u'(c_t(\omega))\varphi_0(\omega)}{u'(c_t(\omega'))\varphi_0(\omega')} \right]^{\frac{1}{1-\psi}}. \quad (28)$$

Lemma 2 provides a partial characterization of the population dynamics of different groups. There are four elements that determine relative population sizes. First, more patient types systematically increase their population share relative to less patient types. At $t \rightarrow \infty$, impatient types tend to eventually disappear from the economy. This is because altruistic parents regard children as added longevity, as a way to increase the stream of future utility flows. Impatient individuals discount future streams more heavily and, therefore, value children less than patient individuals do. As a result, it is efficient for the planner to provide more consumption to impatient individuals in exchange for fewer future family members.¹⁴ Second, the initial distribution of population has a long-lasting impact, one that never dies out since the exponent on $N_0(\omega)/N_0(\omega')$ is equal to 1. Thus, for example, if the initial population is composed mostly of high skilled individuals, then this composition persists over time. Third, types assigned with higher Pareto weights by the planner have more population. Finally, types with lower consumption have a higher population share. We characterize the steady state next.

5.2 Steady state

5.2.1 Population distribution We restrict attention to the set of most patient types $\Omega_p \subseteq \Omega$, which are the only ones with positive population mass in a steady state. Let $\beta(\omega) = \beta$ for all $\omega \in \Omega_p$ and let $\beta \geq \beta(\omega)$ for all $\omega \in \Omega$. Furthermore, consider a steady state in which consumption, population shares, and population are constant. This requires $n(\omega) = 1$ for all types. In that case, (28) simplifies to

$$\frac{N(\omega)}{N(\omega')} = \frac{N_0(\omega)}{N_0(\omega')} \left(\frac{u'(c(\omega))\varphi_0(\omega)}{u'(c(\omega'))\varphi_0(\omega')} \right)^{\frac{1}{1-\psi}}, \quad \omega \in \Omega_p. \tag{29}$$

We can now state our next main result, which is apparent from this equation and the previous discussion.

PROPOSITION 5. *In an interior steady state, (i) only the most patient types, those with the highest $\beta(\omega)$, have positive mass, (ii) the distribution of population depends on the initial distribution and the weights on initial generation, and (iii) the relative population size of a particular type is inversely related to its per capita consumption.*

The second part of Proposition 5 states that the steady state composition of the population depends on the initial composition, a result that is analogous to the dependence of the steady state wealth distribution on initial conditions in the neoclassical growth model (Chatterjee (1994)). But as shown below, in Proposition 7, this dependence has an important added implication in Malthusian economics because the steady state aggregate land–labor ratio and the steady state level of population itself depend on initial conditions. This is unlike the neoclassical growth model where the golden rule level of

¹⁴This result also helps qualify a commonly held view according to which the poor are inherently more impatient, less willing to save, and their large families somehow reflect their impatience. According to our model, if the poor were really impatient, they would have fewer children and their type would eventually disappear from the population.

capital is independent of initial conditions. Efficiency and distribution are interdependent in Malthusian economies. Notice that the steady state composition depends on, but never resembles, the initial composition unless planner’s weights and consumptions are equal across types, which is not the case in general, as we show below, even if planner’s weights are the same.¹⁵

The third part of Proposition 5 shows a fundamental prediction of endogenous population models: an inverse relationship between population size and per capita consumption. The lower is the consumption of a type, the larger is its share of the total population. The reason is that the planner needs to deliver welfare by providing consumption and children to parents. Whenever the planner chooses to use one channel, it downplays the other. We still need to solve for consumption to fully derive the consequences of this inverse relationship.

The following lemma characterizes the steady state distribution of population in terms of consumptions.

LEMMA 3. *Let $g(\omega) \equiv \frac{N(\omega)}{N}$. Then*

$$g(\omega) = \frac{N_0(\omega)[u'(c(\omega))\varphi_0(\omega)]^{1/(1-\psi)}}{\sum_{\omega' \in \Omega_p} N_0(\omega')[u'(c(\omega'))\varphi_0(\omega')]^{1/(1-\psi)}} \quad \text{for all } \omega \in \Omega_p. \quad (30)$$

This lemma provides a simple description of the steady state distribution of population in terms of the given initial distribution and steady state consumption.

5.2.2 *Consumption* Similarly to population dynamics, one can show that only the most patient types have positive consumption in a steady state. According to (17), for consumption to be constant, $\theta_{t+1}(\omega)/\theta_t(\omega) = \mu_{t+1}/\mu_t$ is required. Otherwise, $\theta_{t+1}(\omega)/\theta_t(\omega) < \mu_{t+1}/\mu_t$ refers to a type for which consumption falls and vice versa. Therefore, only the types with the highest ratio $\theta_{t+1}(\omega)/\theta_t(\omega)$ have positive steady state consumption. Moreover, according to (14), $\theta_{t+1}(\omega)/\theta_t(\omega) = \beta(\omega)$ at steady state. Therefore, $\theta_{t+1}(\omega)/\theta_t(\omega)$ is the highest for all $\omega \in \Omega_p$.

The following lemma provides the solution for consumption in terms of the marginal product of labor.

LEMMA 4. *Efficient consumption satisfies*

$$c(\omega) = \frac{\xi(c(\omega))/\beta}{\psi - \xi(c(\omega))} [\eta(\omega) + (\lambda(\omega) - \beta)F_L l(\omega)] \quad \text{for } \omega \in \Omega_p. \quad (31)$$

Equation (31), which is analogous to (25), shows that consumption is proportional to the net financial cost of a child. In particular, consumption is larger for types with a higher cost of raising children, either a higher goods cost $\eta(\omega)$ and/or a higher time

¹⁵Efficient allocations are not time consistent because re-optimizing starting with an initial steady state distribution of population results in a different steady state distribution.

cost $\lambda(\omega)$. The relationship between skills $l(\omega)$ and consumption is slightly more complicated. If $\lambda(\omega) > \beta$, then efficient consumption is higher for highly skilled individuals. But if $\lambda(\omega) < \beta$, then efficient consumption is actually lower for the high skilled. This feature also characterizes the market economics as shown in (5). The intuition is that the net labor cost of a child is $(\lambda(\omega) - \beta)F_L l(\omega)$ since a child takes time from parents, but also adds labor as an adult. The net time cost of a child is thus $(\lambda(\omega) - \beta)F_L l(\omega)$.

We can now state our next main result which follows from (30) and (31).¹⁶

PROPOSITION 6. *Steady state efficient allocations exhibit inequality of consumptions and populations. Types with lower net cost of raising children have lower consumption, but a larger population.*

Proposition 6 is important for at least three reasons. First, as is discussed by Lucas (2002), obtaining an efficient allocation with heterogeneous social classes in Malthusian economies is not trivial. Lucas’ solution, which relies on differences in time discounting, generates inefficient social classes in the presence of binding constraints. Different discount factors would still lead to only one social group surviving at steady state in an efficient allocation. Second, the efficient allocation can rationalize a distribution of social classes in which the poor are a larger fraction of the population. Third, the proposition also states that it is not optimal to end a lineage just because it is of lower skill or poorer. This is in contrast to a literature that argues in favor of limiting the fertility of the poor (e.g., Chu and Koo (1990)). Only impatient types disappear from an efficient allocation.

It is possible to obtain a final solution for consumptions and relative population sizes without knowing the marginal product of labor in the following special Barro–Becker case.

EXAMPLE 1. Suppose $u(c) = c^\xi/\xi$ with $\xi \in (0, 1)$, $\Phi(n) = n^\psi$, $\psi \in (\xi, 1)$, $\lambda(\omega) = \beta$, and $N_0(\omega) = N_0(\omega')$. Then

$$c(\omega) = \frac{\xi}{\psi - \xi} \frac{\eta(\omega)}{\beta} \quad \text{and} \quad \frac{N(\omega)}{N(\omega')} = \left(\frac{\eta(\omega')}{\eta(\omega)} \right)^{\frac{1-\xi}{1-\psi}}. \quad \diamond$$

In this example, consumption is proportional to the goods cost of raising a child $\eta(\omega)$, while the exponent $(1 - \xi)/(1 - \psi) \in (1, \infty)$ controls the extent to which consumption inequality translates into population inequality. Since the restriction $\psi > \xi$ is needed for an interior solution, the exponent is larger than 1. Therefore, population inequality is greater than consumption inequality. For example, if consumption of the rich is 5 times that of the poor, $\eta(\omega')/\eta(\omega) = 5$, and $(1 - \xi)/(1 - \psi) = 2$, then the population of the poor is 25 times that of the rich. The planner in this example is more willing to accept a large share of poor individuals when intergenerational substitution of consumption is particularly low (ξ is low) and/or parental altruism does not decrease sharply with family size (ψ is high).

¹⁶The proof follows from Lemma 3 and Lemma 4 trivially, and, hence, is omitted.

5.2.3 *Average output* A full solution requires us to find the marginal product of labor, which itself requires a solution for the land–labor ratio. For this purpose, rewrite the steady state resource constraint as

$$LF(k, 1; A) = N \sum_{\omega} g(\omega)[c(\omega) + \eta(\omega)],$$

where $k = K/L$. Furthermore, total labor supply relative to population is expressed at steady state by

$$\frac{L}{N} = \sum_{\omega} g(\omega)l(\omega)[1 - \lambda(\omega)]. \tag{32}$$

Dividing these two equations yields

$$F(k, 1; A) = \frac{\sum_{\omega} g(\omega)[c(\omega) + \eta(\omega)]}{\sum_{\omega} g(\omega)l(\omega)[1 - \lambda(\omega)]}. \tag{33}$$

The system of equations (30), (31), and (33), together with the definition $F_L = (1 - \alpha)F(k, 1; A)$, can then be used to solve for the unknowns $g(\omega)$, $c(\omega)$, and k .

5.2.4 *Stagnation* Combining (31) and (33), and using the definition of $\alpha(k, A)$, we obtain

$$c(\omega) = \frac{\xi(c(\omega))/\beta}{\psi(1) - \xi(c(\omega))} \left[+ (\lambda(\omega) - \beta)(1 - \alpha(k, A)) \frac{\sum_{\omega} g(\omega)[c(\omega) + \eta(\omega)]}{\sum_{\omega} g(\omega)l(\omega)[1 - \lambda(\omega)]} l(\omega) \right]. \tag{34}$$

Equations (30), (33), and (34) can be used to solve for $g(\omega)$, $c(\omega)$, and k . Since K is not part of the system, it follows that land discoveries do not affect individual consumption or the composition of population. Furthermore, if technological progress is land-augmenting, the increase in A does not affect $\alpha(k, A)$, which is equal to $\alpha(Ak)$. Hence, $c(\omega)$ and $g(\omega)$ are also independent of A in that case. Once we solve for k , aggregate labor supply can be solved as $L = K/k$, while N is solved from (32). The following proposition summarizes these results. The proof is similar to that of Proposition 4 and, hence, is omitted.

PROPOSITION 7. *Suppose $\varphi_{t+1}(\omega) = 0$ for $t \geq 0$ and $\omega \in \Omega$, $\Phi(n) = n^\psi$, and the steady state is interior. Then (i) in steady state, optimal consumption is independent of the amount of land and optimal population is proportional to the amount of land, (ii) if technological progress is land-augmenting, then optimal consumption is independent of the level of technology and population increases proportionally with the level of technology, and (iii) optimal allocations depend on the initial distribution of population.*

6. STOCHASTIC CASE

The deterministic version of the model considered so far counterfactually predicts equal fertility among different social groups. Malthus, however, observed that fertility rates were higher among the poor. We now show that a version of the model with stochastic types can generate differential fertility. For tractability, we once again assume $\varphi_{t+1}(\omega^{t+1}) = 0$ for all $t \geq 0$,¹⁷ assume $\beta(\omega) = \beta$, and use the Barro–Becker functional forms $\Phi(n) = n^\psi$ and $u(c) = c^\xi/\xi$. Equation (14) can be simplified, using (17) and the law of motion for population, (8), as

$$\beta(\omega_t) \frac{\Phi(n_t(\omega^t))}{n_t(\omega^t)} = \frac{\mu_{t+1}}{\mu_t} \frac{u'(c_t(\omega^t))}{u'(c_{t+1}(\omega^{t+1}))} \quad \text{for } \omega^{t+1} \in \Omega_{t+1}. \tag{35}$$

Since this equation is the same for all $\omega_{t+1} \in \Omega$ for a given $\omega^t \in \Omega_t$, it follows that all children within a family have the same consumption:

$$c_{t+1}([\omega^t, \omega_{t+1}]) = c_{t+1}(\omega^t) \quad \text{for all } \omega_{t+1} \in \Omega.$$

This is a standard risk-sharing result that is obtained regardless of whether fertility is endogenous or exogenous: absent aggregate uncertainty, smoothing consumption across children or next period states is socially optimal. The result, however, does not state that children’s consumption is equal to parents’ consumption. Consumption smoothing across time is not guaranteed.

The following proposition extends the results of the previous sections by characterizing a child’s consumption as proportional to the *expected* net costs of raising that child. A full characterization of efficient allocations is provided in the proof of this proposition in the [Appendix](#). This result implies a strong degree of history independence.

PROPOSITION 8. *Optimal allocations satisfy $c_{t+1}(\omega^{t+1}) = c_{t+1}(\omega_t)$ and $n_t(\omega^t) = n_t(\omega_{t-1}, \omega_t)$. In particular,*

$$c_{t+1}(\omega_t) = \frac{\xi}{\psi - \xi} \left\{ \begin{array}{l} \frac{\mu_t}{\mu_{t+1}} [\eta(\omega_t) + F_L(K, L_t; A)l(\omega_t)\lambda_t(\omega_t)] \\ -F_L(K, L_{t+1}; A)E_t(l(\omega_{t+1})|\omega_t) \end{array} \right\} \tag{36}$$

and $n_t(\omega_{t-1}, \omega_t)$ satisfies

$$\beta(\omega_t)\Phi'(n_t(\omega_{t-1}, \omega_t)) = \psi \frac{\mu_{t+1}}{\mu_t} \frac{u'(c_t(\omega_{t-1}))}{u'(c_{t+1}(\omega_t))}$$

for all $\omega_{t-1}, \omega_t \in \Omega, t > 0$.

Regarding consumption, the proposition states that only parental type ω_t determines consumption of her children to the extent that it determines the cost of raising

¹⁷It is represented by SW₂ or a special case of those discussed in SW₁ when the social planner puts positive weights only on initial olds and cares about future generation through the initial generation.

the child and the expected labor supply of the child. For consumption to be equalized across parents, the cost of raising children net of children’s expected labor supply must be equal. If not, then full consumption smoothing is not socially optimal. Efficient consumption is random. This is in contrast to the exogenous fertility model in which individual consumption is not random as it depends only on ω_0 rather than on the full ancestors’ history ω^t .¹⁸ Finally, substituting (36) into (35), it follows that $n_t(\omega^t) = n_t(\omega_{t-1}, \omega_t)$ so that the number of children depends only on parental and grandparental types.

Another key feature of consumption, stated in the proposition, is the lack of memory or lack of persistence result. Specifically, $c_{t+1}(\omega^{t+1}) = c_{t+1}(\omega_t)$ means that the only part of history that matters for efficient individual consumption is ω_t , while the remaining part, $[\omega_0, \omega_1, \dots, \omega_{t-1}]$, is irrelevant. Thus, the child of lucky parents, parents with a favorable ω_t , enjoy high consumption even if all the previous ancestors were unlucky and have low consumption. Hosseini et al. (2013) and Alvarez (1999) obtain similar lack of persistence results in incomplete market models.

6.1 Steady state

Consider now stationary steady state allocations in which $n_t(\omega_{t-1}, \omega_t) = n(\omega_{t-1}, \omega_t)$, $c_t(\omega_{t-1}) = c(\omega_{t-1})$, and $N_t = N$. Let $Q_t \equiv \mu_t/\mu_{t+1}$ be the planner’s shadow gross return and let $g(\omega_{t-1}, \omega_t) \equiv N(\omega_{t-1}, \omega_t)/N_t$ be the population share with recent history (ω_{t-1}, ω_t) at steady state where $N(\omega_{t-1}, \omega_t) \equiv \sum_{\omega^{t-2}} N_t(\omega^t)$. The following lemma summarizes the system of equations and unknowns that describe the stationary steady state.

LEMMA 5. *Steady state allocations $c(\omega)$, $n(\omega_{-1}, \omega)$, $g(\omega_{-1}, \omega)$, Q , L , and N are solved from the systems of equations*

$$c(\omega) = \frac{\xi Q}{\psi - \xi} [\eta(\omega) + F_L l(\omega) \lambda(\omega) - F_L E[l(\omega_{+1})|\omega]/Q] \quad (37)$$

$$n(\omega_{-1}, \omega) = \left[\beta Q \frac{u'(c(\omega))}{u'(c(\omega_{-1}))} \right]^{\frac{1}{1-\psi}} \quad (38)$$

$$g(\omega, \omega_{+1}) = \sum_{\omega_{-1}} n(\omega_{-1}, \omega) \pi(\omega_{+1}, \omega) g(\omega_{-1}, \omega) \quad (39)$$

$$\sum_{\omega_{-1}} \sum_{\omega} g(\omega_{-1}, \omega) n(\omega_{-1}, \omega) = 1 \quad (40)$$

$$F\left(\frac{K}{L}, 1; A\right) = \frac{N}{L} \sum_{\omega_{-1}} \sum_{\omega} g(\omega_{-1}, \omega) [c(\omega_{-1}) + \eta(\omega) n(\omega_{-1}, \omega)] \quad (41)$$

¹⁸When fertility is exogenously given to be 1, the first-order condition with respect to $U_{t+1}(\omega^{t+1})$ derived in the Appendix can be iterated as $\theta_t(\omega^t) = \beta^t \theta_0(\omega^0)$. By the first-order condition with respect to consumption, people living in the same generation and coming from the same initial old ancestor (or with the same initial old ancestor’s weight) have the same level of consumption.

$$\frac{L}{N} = \sum_{\omega_{-1}} \sum_{\omega} g(\omega_{-1}, \omega) l(\omega) (1 - \lambda(\omega) n(\omega_{-1}, \omega)), \tag{42}$$

where $F_L = (1 - \alpha(K/L, A))F(K/L, 1; A)$.

Equation (37) shows the consumption of an individual whose parent is of type ω . Consumption is positively associated with parental costs of raising children and parental skills, and it is negatively associated with the expected skills of the child. Equation (38) shows fertility differentials among different types. Optimal fertility depends on parental and grandparental types. Given grandparental types, parents with particularly low costs of raising children would have more children than otherwise. Also, given parental types, grandparents with particularly high costs of raising children would have more grandchildren. Equation (40), which in principle serves to solve Q , restricts fertility to be 1 on average. Equations (41) and (42) are resource constraints of goods and labor.

The next proposition shows that the stagnation property still holds in the stochastic case.

PROPOSITION 9. *Suppose the steady state is interior. Then steady state optimal consumption is independent of the amount of land and optimal population increases proportionally with the amount of land. Furthermore, if technological progress is land-augmenting, then optimal consumption is independent of the level of technology and population increases proportionally with the level of technology.*

To summarize, in addition to stagnation, the key properties of the stochastic steady state are differential fertility and heterogeneous social groups. Moreover, all types or social groups are represented in a steady state even if their initial population is zero as long as π is nonreducible.

7. DECENTRALIZATION

This section extends Section 2 to a stochastic environment. We show that when $\varphi_{t+1}(\omega^{t+1}) = 0$ for all $t \geq 0$, the social planner’s problem characterized by SW_2 can be decentralized by a competitive market economy with a fixed amount of land.¹⁹ The basic environment is the same with the social planner’s problem. Parents are altruistic toward children in the form of Barro and Becker. We follow previous notation except for adding a superscript c to allocations of consumption, fertility, population, labor, and land to represent competitive equilibrium allocations. Let $k_t^c(\omega^t)$ denote the amount of land each adult living in period t is endowed with when his family history is $\omega^t \in \Omega_t$. It can be regarded as the bequest from parents and can be traded at the price p_t . Land can also be rented at the rental rate r_t . Parents are allowed to sign a contingent contract

¹⁹When $\varphi_{t+1}(\omega^{t+1}) > 0$ for some ω^{t+1} , there is a wedge that makes decentralization with lump-sum instruments unfeasible. This issue arises even if fertility is exogenous and was first carefully studied by Bernheim (1989). But as shown in Section 4, and consistent with Bernheim’s findings, under Assumption 1, the planner in the limit behaves just like a planner with $\varphi_{t+1}(\omega^{t+1}) = 0$ for all ω^{t+1} .

based on children's type ω_{t+1} that is buying or selling land for the next generation, depending on each one's realization of ability. Let $q_t(\omega_{t+1}, \omega_t)$ be the time t price of one unit of land contingent on the time $t + 1$ realization of child's ability being ω_{t+1} and the time t realization being ω_t . People work in a competitive labor market. Let $w_t(\omega_t)$ be the wage of type ω_t at time t .

Initial parents maximize their own dynasty's welfare:

$$\max_{\{c_t(\omega^t), n_t(\omega^t), k_{t+1}(\omega^{t+1})\}_{t=0, \omega^t \in \Omega_t}^\infty} E_0 \left[\sum_{t=0}^\infty \beta^t \sum_{\omega^t \in \Omega_t} \prod_{j=0}^{t-1} \Phi(n_j(\omega^j)) u(c_t(\omega^t)) \right]. \tag{43}$$

Households are subject to the constraints

$$\begin{aligned} c_t(\omega^t) + \eta(\omega_t)n_t(\omega^t) + n_t(\omega^t) \sum_{\omega_{t+1}} q_t(\omega_{t+1}, \omega_t)k_{t+1}(\omega^{t+1}) \\ \leq w_t(\omega_t)(1 - \lambda(\omega_t)n_t(\omega^t)) + (r_t + p_t)k_t(\omega^t) \quad \text{for } \omega^t \in \Omega_t, t \geq 0, \end{aligned} \tag{44}$$

where initial population and land-holding $\{N_0(\omega_0), k_0(\omega_0)\}_{\omega_0 \in \Omega}$ are given. Assume $\Phi(n) = n^\psi$ and $u(c) = c^\xi/\xi$.

Firms hire labor on a competitive labor market, and people rent land to firms on a competitive land market. The competitive equilibrium of this problem is characterized by the following proposition.

PROPOSITION 10. *Given initial levels of land and population $\{k_0(\omega_0), N_0(\omega_0)\}_{\omega_0 \in \Omega}$, equilibrium allocations and prices are solved by the system of equations, for $t \geq 0$,*

$$r_t = F_K(K, L_t^c; A), \quad w_t(\omega_t) = F_L(K, L_t^c; A)l(\omega_t),$$

$$q_t(\omega_{t+1}, \omega_t) = p_t \pi(\omega_{t+1}, \omega_t),$$

$$c_{t+1}^c(\omega^{t+1}) = \frac{\xi}{\psi - \xi} \left[\frac{r_{t+1} + p_{t+1}}{p_t} [\eta(\omega_t) + w_t(\omega_t)\lambda(\omega_t)] - E_t[w_{t+1}(\omega_{t+1})] \right], \tag{45}$$

$$\beta \frac{\Phi(n_t^c(\omega^t))}{n_t^c(\omega^t)} = \frac{p_t}{r_{t+1} + p_{t+1}} \frac{u'(c_t^c(\omega^t))}{u'(c_{t+1}^c(\omega^{t+1}))}, \tag{46}$$

$$K = \sum_{\omega^t \in \Omega_t} N_t^c(\omega^t) k_t^c(\omega^t),$$

(44), (7), and (8).

Rewriting (46) and iterating, we obtain

$$p_t = \sum_{j=0}^\infty \beta^{j+1} \left(\prod_{k=0}^j \frac{\Phi(n_{t+k}^c(\omega^{t+k}))}{n_{t+k}^c(\omega^{t+k})} \right) \frac{u'(c_{t+j+1}^c(\omega^{t+j+1}))}{u'(c_t^c(\omega^t))} r_{t+j+1}$$

for any family history $\{\omega^t\}_{t=0}^\infty$. The parameter p_0 is given by this formula when $t = 0$. Price is the present value of rents discounted by a rate that depends on the standard discount factor in Φ as well as the fertility rates.

COROLLARY 1. *The competitive equilibrium consumption of every individual depends on parental type, but not on one's own type, e.g., $c_{t+1}^c(\omega^{t+1}) = c_{t+1}^c(\omega_t)$. As a result, fertility depends on both parents' and grandparents' types, e.g., $n_t^c(\omega^t) = n_t^c(\omega_{t-1}, \omega_t)$.²⁰*

The proof of this corollary is straightforward according to the equalities in (45) and (46), and it is omitted. Finally, we show the correspondence of the competitive equilibrium with contingent assets with the planner's problem. The following proposition shows that the competitive equilibrium corresponds to a social planner's problem and it is, hence, A- and P-efficient.

PROPOSITION 11. *For a given initial distribution of land $\{k_0(\omega_0)\}_{\omega_0 \in \Omega}$, the optimal allocations of the decentralized equilibrium with contingent contracts solve SW_2 for a properly selected planner's weights $\{\varphi_0(\omega_0)\}_{\omega_0 \in \Omega}$ and, hence, it is A- and P-efficient.*

Next we show that the problem of the social planner who directly cares only about the initial generation can be decentralized by a competitive equilibrium with an initial land distribution.

PROPOSITION 12. *Given social planner's weights $\{\varphi_0(\omega_0)\}_{\omega_0 \in \Omega}$ on the initial generation with population $\{N_0(\omega_0)\}_{\omega_0 \in \Omega}$, there exists an initial distribution of land $\{k_0(\omega_0)\}_{\omega_0 \in \Omega}$ under which the competitive equilibrium with contingent assets decentralizes the social planner's problem characterized by SW_2 .*

8. CONCLUDING COMMENTS

Existing literature shows that equilibrium allocations obtained under endogenous fertility differ sharply from those obtained under exogenous fertility. This observation motivates us to better understand social optima when population is endogenous. This article characterizes efficient allocations in fixed resource economies with endogenous fertility.

The pre-industrial world was to a large extent Malthusian. As documented by [Ashraf and Galor \(2011\)](#), periods characterized by improvements in technology or in the availability of land eventually lead to a larger, but not richer, population. This is remarkable given the diversity of political, social, religious, geographical, cultural, and economic environments they consider, some arguably more advanced than others. We find that stagnation, inequality, high population of the poor, and differential fertility can naturally arise as an optimal social choice. Our findings could shed light on why the Malthusian "trap" was so pervasive in pre-industrial societies. We also show that it is not the irrational animal spirit of human beings, as suggested by Malthus, that ultimately explains the stagnation. Stagnation can be the result of an optimal choice between the quality and the quantity of life in the presence of limited natural resources.

Finally, we expect that our methodology will further facilitate the study of demographics issues using tools of welfare economics and macroeconomics.

²⁰We have $n_0(\omega_{-1}, \omega_0) = n_0(\omega_0)$.

APPENDIX

A.1 Proofs of propositions and lemmas

PROOF OF PROPOSITION 1. Let (n^*, c^*) solve the planner’s problem. Suppose, to the contrary, that an alternative feasible allocation (\hat{n}, \hat{c}) that P-dominates (n^*, c^*) exists. Let $\bar{U}_t(\omega^t)$ denote the utility of a potential agent with history ω^t under the alternative plan (\hat{n}, \hat{c}) and let $U_t^*(\omega^t)$ denote the utility under (n^*, c^*) . For (\hat{n}, \hat{c}) to P-dominate (n^*, c^*) , it must be the case that $\bar{U}_t(\omega^t) \geq U_t^*(\omega^t)$ for all $\omega^t \in \Omega_t$ and all $t \geq 0$ with strict inequality holds for at least one ω^t . (i) Under SW_1 , if $\varphi_t(\omega^t) > 0$, then $\varphi_t(\omega^t)\bar{N}_t(\omega^t) > 0$ for all $t \geq 0$ and $\omega^t \in \Omega_t$ so that (11) is larger under \bar{U}_t than under U_t^* , which contradicts the statement that (n^*, c^*) maximizes social welfare. (ii) Look at the social welfare function SW_2 . If $\bar{U}_0(\omega_0) \geq U_0^*(\omega_0)$ for all $\omega_0 \in \Omega_0$ with strict inequality for some $\omega_0 \in \Omega_0$, then (n^*, c^*) will not maximize social welfare since $N_0(\omega_0) > 0$ for all $\omega_0 \in \Omega_0$. Social welfare still could be equal under both allocations, but this would violate the assumed uniqueness of the maximizer. \square

PROOF OF PROPOSITION 2. The proof of this proposition is quite similar to that of the P-efficiency. Let (n^*, c^*) solve the planner’s problem. Suppose, to the contrary, that an alternative feasible allocation (\hat{n}, \hat{c}) that A-dominates (n^*, c^*) exists. Let $\bar{U}_0(\omega_0)$ denote the utility of an agent living in period 0 with type ω_0 under the alternative plan (\hat{n}, \hat{c}) and let $U_0^*(\omega_0)$ denote the utility under (n^*, c^*) . For (\hat{n}, \hat{c}) to A-dominate (n^*, c^*) , it must be the case that $\bar{U}_0(\omega_0) \geq U_0^*(\omega_0)$ for all $\omega_0 \in \Omega_0$ with strict inequality holds for at least one ω^t . If $\varphi_0(\omega_0) > 0$ for all $\omega_0 \in \Omega_0$, then (n^*, c^*) would not maximize social welfare. If $\varphi_0(\omega_0)$ is zero for some ω_0 and the solution to the planner’s problem maximizing SW_2 is unique, then it violates the assumed uniqueness of the maximizer. \square

PROOF OF PROPOSITION 3. The Lagrangian of the planner’s problem is

$$\begin{aligned} \mathcal{L} = & \sum_{t=0} \sum_{\omega^t} \varphi_t(\omega^t) N_t(\omega^t) U_t(\omega^t) \\ & + \sum_{t=0}^{\infty} \sum_{\omega^t} \theta_t(\omega^t) N_t(\omega^t) [u(c_t(\omega^t)) + \beta(\omega_t) \Phi(n_t(\omega^t)) E_t U_{t+1}(\omega^{t+1}) - U_t(\omega^t)] \\ & + \sum_{t=0}^{\infty} \sum_{\omega^{t+1}} \gamma_{t+1}(\omega^{t+1}) [N_{t+1}(\omega^{t+1}) - n_t(\omega^t) \pi(\omega_{t+1}, \omega_t) N_t(\omega^t)] \\ & + \sum_{t=0}^{\infty} \mu_t \left[F(K, L_t; A) - \sum_{\omega^t} N_t(\omega^t) [c_t(\omega^t) + \eta(\omega_t) n_t(\omega^t)] \right] \\ & + \sum_{t=0}^{\infty} \kappa_t \left[\sum_{\omega^t} N_t(\omega^t) l(\omega_t) [1 - \lambda_t(\omega_t) n_t(\omega^t)] - L_t \right]. \end{aligned}$$

First-order conditions with respect to $\{U_0(\omega^0), U_{t+1}(\omega^{t+1}), N_{t+1}(\omega^{t+1}), n_t(\omega^t), c_t(\omega^t), L_t\}_{\omega^t \in \Omega_t, t \geq 0}$ are (13), (14), (15), (16), (17), and (18). In the deterministic case, the first-order conditions with respect to $n_t, N_{t+1}, U_t,$ and c_t can be simplified as

$$\theta_t \beta \Phi_n(n_t) U_{t+1} = \mu_t \eta + \kappa_t l \lambda_t + \gamma_{t+1} \tag{47}$$

$$\varphi_{t+1} U_{t+1} + \kappa_{t+1} l [1 - \lambda_{t+1} n_{t+1}] + \gamma_{t+1} = \mu_{t+1} [c_{t+1} + \eta n_{t+1}] + n_{t+1} \gamma_{t+2} \tag{48}$$

$$\begin{aligned} \theta_{t+1} N_{t+1} &= \varphi_{t+1} N_{t+1} + \theta_t N_t \beta \Phi(n_t) \\ \theta_t u'(c_t) &= \mu_t. \end{aligned} \tag{49}$$

Substituting γ_{t+1} and γ_{t+2} out of (48) using (47), and then using (18) and (17) to substitute κ_{t+1} and μ_t , respectively, out, we obtain

$$\begin{aligned} \varphi_{t+1} U_{t+1} + \kappa_{t+1} l [1 - \lambda_{t+1} n_{t+1}] + \theta_t \beta \Phi_n(n_t) U_{t+1} - \mu_t \eta - \kappa_t l \lambda_t \\ = \mu_{t+1} [c_{t+1} + \eta n_{t+1}] + n_{t+1} [\theta_{t+1} \beta \Phi_n(n_{t+1}) U_{t+2} - \mu_{t+1} \eta - \kappa_{t+1} l \lambda_{t+1}] \end{aligned}$$

so

$$\begin{aligned} \varphi_{t+1} U_{t+1} + \theta_t \beta \Phi_n(n_t) U_{t+1} &= \theta_{t+1} u'(c_{t+1}) \left(c_{t+1} - F_{L,t+1} l + \frac{\mu_t}{\mu_{t+1}} (\eta + F_{L,t} l \lambda_t) \right) \\ &\quad + \theta_{t+1} \frac{n_{t+1} \Phi_n(n_{t+1})}{\Phi(n_{t+1})} (U_{t+1} - u(c_{t+1})). \end{aligned} \tag{50}$$

Iterating (49), we can get

$$\begin{aligned} \theta_{t+1} &= \varphi_{t+1} + \beta \frac{\Phi(n_t)}{n_t} \left[\varphi_t + \beta \frac{\theta_{t-1} \Phi(n_{t-1})}{n_{t-1}} \right] \\ &= \sum_{m=1}^{t+1} \varphi_m \beta^{t+1-m} \prod_{j=m}^t \frac{\Phi(n_j)}{n_j} + \beta^{t+1} \prod_{j=0}^t \frac{\Phi(n_j)}{n_j} \theta_0 \\ &= \sum_{m=0}^{t+1} \varphi_m \beta^{t+1-m} \prod_{j=m}^t \frac{\Phi(n_j)}{n_j}. \end{aligned}$$

Given that the altruism function takes the Barro–Becker form $\Phi(n) = n^\psi$, then

$$\theta_{t+1} = \beta^{t+1} N_{t+1}^{\psi-1} \sum_{m=0}^{t+1} \varphi_m \beta^{-m} N_m^{1-\psi}.$$

Plugging this result into (50) gives

$$\begin{aligned} (1 - \psi) \varphi_{t+1} U_{t+1} \\ = \beta^{t+1} N_{t+1}^{\psi-1} \left(\sum_{m=0}^{t+1} \varphi_m \beta^{-m} N_m^{1-\psi} \right) u'(c_{t+1}) \left(c_{t+1} - F_{L,t+1} l + \frac{\mu_t}{\mu_{t+1}} (\eta + F_{L,t} l \lambda_t) \right) \\ - u(c_{t+1}) \beta^{t+1} N_{t+1}^{\psi-1} \left(\sum_{m=0}^{t+1} \varphi_m \beta^{-m} N_m^{1-\psi} \right) \psi. \end{aligned}$$

Use this equation to express c_{t+1} as

$$c_{t+1} = F_{L,t+1}l - \frac{\mu_t}{\mu_{t+1}}(\eta + F_{L,t}l\lambda_t) + \frac{u(c_{t+1})}{u'(c_{t+1})c_{t+1}}\psi c_{t+1} + \frac{1}{u'(c_{t+1})}\beta^{-(t+1)}N_{t+1}^{1-\psi} \left(\sum_{m=0}^{t+1} \varphi_m \beta^{-m} N_m^{1-\psi} \right)^{-1} (1 - \psi)\varphi_{t+1}U_{t+1}.$$

Under the assumed form of $\Phi(\cdot)$, $\psi = \frac{n_t \Phi_n(n_t)}{\Phi(n_t)} = \frac{n_{t+1} \Phi_n(n_{t+1})}{\Phi(n_{t+1})}$, we can collect terms and solve for consumption as in (24). □

PROOF OF LEMMA 1. Consider the steady state situation in which N and c are constant. In that case, $n = 1$ and (21) can be written as $\theta_{t+1}/\theta_t = \beta + \varphi_{t+1}/\theta_t \geq \beta$. Under Assumption 1, the ratio φ_{t+1}/θ_t goes to zero in the limit. It is easy to show that the Lagrangian multipliers grow at constant rate at steady state. To see this, first look at (17) and (18), which imply that θ_t , μ_t , and κ_t grow at the same rate at steady state. Using the steady state version of (16), we can see that

$$\frac{\theta_{t+1}}{\theta_t} = \frac{\theta_{t+1}\Phi_n(1)U}{\theta_t\Phi_n(1)U} = \frac{\frac{\mu_{t+1}}{\mu_t}\mu_t\eta + \frac{\kappa_{t+1}}{\kappa_t}\kappa_t l\lambda + \frac{\gamma_{t+2}}{\gamma_t + 1}\gamma_{t+1}}{\mu_t\eta + \kappa_t l\lambda + \gamma_{t+1}}$$

so

$$\frac{\theta_{t+1}}{\theta_t}\mu_t\eta + \frac{\theta_{t+1}}{\theta_t}\kappa_t l\lambda + \frac{\theta_{t+1}}{\theta_t}\gamma_{t+1} = \frac{\mu_{t+1}}{\mu_t}\mu_t\eta + \frac{\kappa_{t+1}}{\kappa_t}\kappa_t l\lambda + \frac{\gamma_{t+2}}{\gamma_t + 1}\gamma_{t+1}.$$

Since θ_t , μ_t , and κ_t grow at the same rate at steady state, this equation can be reduced to

$$\frac{\theta_{t+1}}{\theta_t} = \frac{\gamma_{t+2}}{\gamma_{t+1}}.$$

Then γ_t grows at the same rate with θ_t , μ_t , and κ_t at the steady state, which implies that γ_t/μ_t is a constant at steady state. Hence, γ_{t+1}/γ_t is a constant by (23) and so are other Lagrangian parameters. Therefore, at steady state, $\theta_{t+1}/\theta_t = \mu_{t+1}/\mu_t = \gamma_{t+1}/\gamma_t = \kappa_{t+1}/\kappa_t = \beta$. Then the steady state consumption in (24) reduces to (25). □

PROOF OF PROPOSITION 4. For the first part of this proposition, A is given. Then c , F_L , and K/L are fully determined by the three equations (25), (26), and (27). Hence consumption is independent of the amount of land, while efficient population increases proportionally with the amount of land. For the second part, when $\hat{F}(AK, L) = F(K, L; A)$,

$$\hat{F}\left(\frac{AK}{N}, 1 - \lambda\right) = F\left(\frac{K}{N}, 1 - \lambda; A\right),$$

then

$$\alpha\left(\frac{K}{L}, A\right) = \frac{K}{L} \frac{F_K\left(\frac{K}{L}, 1; A\right)}{F\left(\frac{K}{L}, 1; A\right)} = \frac{A\hat{F}_1(AK, L)K}{\hat{F}(AK, L)} = \frac{\hat{F}_1(AK/L, 1)}{\hat{F}(AK/L, 1)} \frac{AK}{L} = \hat{\alpha}\left(\frac{AK}{L}\right)$$

$$F_L = \frac{1 - \hat{\alpha} \left(\frac{AK}{L} \right)}{1 - \lambda} (c + \eta), \tag{51}$$

where

$$F_L = \left(1 - \hat{\alpha} \left(\frac{AK}{L} \right) \right) \hat{F} \left(\frac{AK}{L}, 1 \right). \tag{52}$$

Then c , F_L , and AK/L are solved by (25), (51), and (52), which are all independent of A . □

PROOF OF LEMMA 2. Let $s_t(\omega) \equiv \theta_t(\omega)N_t(\omega)$. Equation (14), given that $\varphi_t(\omega) = 0$ for all $t > 0$ and $\omega \in \Omega$ is assumed, can then be written as $s_{t+1}(\omega) = \beta(\omega)s_t(\omega)\Phi(n_t(\omega))$. By iterating, we obtain $s_t(\omega) = \beta(\omega)^t s_0(\omega) \prod_{i=0}^{t-1} \Phi(n_i(\omega))$, $t > 0$. Recalling that $\Phi(n) = n^\psi$ is assumed in Section 4, it follows that

$$s_t(\omega) = \theta_0(\omega)(N_0(\omega))^{1-\psi} \beta(\omega)^t (N_t(\omega))^\psi. \tag{53}$$

Now (17) can be written as $\mu_t N_t(\omega) = s_t(\omega)u'(c_t(\omega))$. Therefore,

$$\frac{N_t(\omega)}{N_t(\omega')} = \frac{s_t(\omega)u'(c_t(\omega))}{s_t(\omega')u'(c_t(\omega'))}.$$

Substituting (53) into this equation gives

$$\frac{N_t(\omega)}{N_t(\omega')} = \frac{\theta_0(\omega)(N_0(\omega))^{1-\psi} \beta(\omega)^t (N_t(\omega))^\psi u'(c_t(\omega))}{\theta_0(\omega')(N_0(\omega'))^{1-\psi} \beta(\omega')^t (N_t(\omega'))^\psi u'(c_t(\omega'))}.$$

Finally, use (13) to substitute $\theta_0(\omega)$ and solve for $\frac{N_t(\omega)}{N_t(\omega')}$ to obtain (28). □

PROOF OF LEMMA 3. According to (29),

$$\frac{N(\omega')}{N(\omega)} = \frac{N_0(\omega')}{N_0(\omega)} \left(\frac{u'(c(\omega'))}{u'(c(\omega))} \frac{\varphi_0(\omega')}{\varphi_0(\omega)} \right)^{\frac{1}{1-\psi}}.$$

Adding $N(\omega)$ over ω gives

$$\begin{aligned} N &= \sum_{\omega'} N(\omega') \\ &= \frac{N(\omega)}{N_0(\omega)[u'(c(\omega))\varphi_0(\omega)]^{1/(1-\psi)}} \sum_{\omega'} N_0(\omega')[u'(c(\omega'))\varphi_0(\omega')]^{1/(1-\psi)} \end{aligned}$$

and, therefore,

$$g(\omega) = \frac{N(\omega)}{N} = \frac{N_0(\omega)[u'(c(\omega))\varphi_0(\omega)]^{1/(1-\psi)}}{\sum_{\omega \in \Omega_p} N_0(\omega')[u'(c(\omega'))\varphi_0(\omega')]^{1/(1-\psi)}} \quad \text{for all } \omega \in \Omega_p. \tag{54}$$

□

PROOF OF LEMMA 4. Rewrite (15) using (18) and evaluate it at the steady state:

$$1 = \frac{\mu_{t+1}}{\gamma_{t+1}(\omega)} [c(\omega) + \eta(\omega) - F_L l(\omega)(1 - \lambda(\omega))] + \frac{\gamma_{t+2}(\omega)}{\gamma_{t+1}(\omega)}.$$

Since $\gamma_{t+2}(\omega)/\gamma_{t+1}(\omega)$ is constant in steady state, then $\mu_{t+1}/\gamma_{t+1}(\omega)$ needs to be constant for this equation to hold, which means that $\gamma_{t+1}(\omega)/\gamma_t(\omega) = \mu_{t+1}/\mu_t = \beta$. The last equality holds by (17) and (21). Therefore, the previous equation can be written as

$$\frac{\gamma_t(\omega)}{\mu_t} = \frac{1}{1 - \beta} [c(\omega) + \eta(\omega) - F_L l(\omega)(1 - \lambda(\omega))]. \tag{54}$$

This expression states that the value of an immigrant in terms of goods, $\gamma_t(\omega)/\mu_t$, is the net present value of the net cost. In steady state, $U \equiv U(c(\omega)) = u(c(\omega))/(1 - \beta)$. Use this result, (17) and (18) to rewrite (16) as

$$\frac{\beta\Phi'(1)}{1 - \beta} \frac{u(c(\omega))}{u'(c(\omega))} = \eta(\omega) + F_L l(\omega)\lambda(\omega) + \beta \frac{\gamma_t(\omega)}{\mu_t}. \tag{55}$$

Combine (54) and (55) to solve for consumption as

$$c(\omega) = \frac{\xi(c(\omega))}{\beta\Phi'(1) - \beta\xi(c(\omega))} [\eta(\omega) + (\lambda(\omega) - \beta)F_L l(\omega)].$$

We can obtain the result using $\Phi(n) = n^\psi$. □

PROOF OF PROPOSITION 8. The Lagrange of the social planner’s problem is

$$\begin{aligned} \mathcal{L} = & \sum_{\omega_0 \in \Omega} \varphi_0(\omega_0) N_0(\omega_0) U_0(\omega_0) \\ & + \sum_{t=0}^{\infty} \sum_{\omega^t} \theta_t(\omega^t) N_t(\omega^t) [u(c_t(\omega^t)) + \beta(\omega_t)\Phi(n_t(\omega^t))E_t U_{t+1}(\omega^{t+1}) - U_t(\omega^t)] \\ & + \sum_{t=0}^{\infty} \sum_{\omega^{t+1}} \gamma_{t+1}(\omega^{t+1}) [N_{t+1}(\omega^{t+1}) - n_t(\omega^t)\pi(\omega_{t+1}, \omega_t)N_t(\omega^t)] \\ & + \sum_{t=0}^{\infty} \mu_t \left[F(K, L_t; A) - \sum_{\omega^t} N_t(\omega^t) [c_t(\omega^t) + \eta(\omega_t)n_t(\omega^t)] \right] \\ & + \sum_{t=0}^{\infty} \kappa_t \left[\sum_{\omega^t} N_t(\omega^t) l(\omega_t) [1 - \lambda_t(\omega_t)n_t(\omega^t)] - L_t \right]. \end{aligned}$$

First-order conditions are with respect to

$$\begin{aligned} & \{n_t(\omega^t), N_{t+1}(\omega^{t+1}), U_{t+1}(\omega^{t+1}), U_0(\omega_0), c_t(\omega^t), L_t\}_{\omega^t \in \Omega, t \geq 0} : \\ & \theta_t(\omega^t)\beta(\omega_t)\Phi_n(n_t(\omega^t))E_t U_{t+1}(\omega^{t+1}) \\ & = \mu_t \eta(\omega_t) + \kappa_t l(\omega_t)\lambda_t(\omega_t) + \sum_{\omega^{t+1}|\omega^t} \gamma_{t+1}(\omega^{t+1})\pi(\omega_{t+1}, \omega_t) \end{aligned}$$

$$\begin{aligned} & \kappa_{t+1}l(\omega_{t+1})[1 - \lambda_{t+1}(\omega_{t+1})n_{t+1}(\omega^{t+1})] + \gamma_{t+1}(\omega^{t+1}) \\ &= \mu_{t+1}[c_{t+1}(\omega^{t+1}) + \eta(\omega_{t+1})n_{t+1}(\omega^{t+1})] \\ & \quad + \sum_{\omega_{t+2}|\omega_{t+1}} n_{t+1}(\omega^{t+1})\gamma_{t+2}(\omega^{t+2})\pi(\omega_{t+2}, \omega_{t+1}) \\ \theta_{t+1}(\omega^{t+1}) &= \theta_t(\omega^t)\beta(\omega_t)\frac{\Phi(n_t(\omega^t))}{n_t(\omega^t)} \\ \varphi_0(\omega_0) &= \theta_0(\omega_0) \\ \theta_t(\omega^t)u'(c_t(\omega^t)) &= \mu_t \\ \mu_t F_2(K, L_t; A) &= \kappa_t. \end{aligned}$$

For period 0, using first-order conditions with respect to $U_0(\omega_0)$ and $c_0(\omega_0)$, we obtain

$$\frac{u'(c_0(\omega_0))}{u'(c_0(\tilde{\omega}_0))} = \frac{\varphi_0(\tilde{\omega}_0)}{\varphi_0(\omega_0)} \quad \text{for all } \omega_0, \tilde{\omega}_0 \in \Omega. \tag{56}$$

By substituting out κ_t and $\theta_t(\omega^t)$ in the first-order condition with respect to $n_t(\omega^t)$, we write

$$E_t U_{t+1}(\omega^{t+1}) = \frac{u'(c_t(\omega^t))}{\beta(\omega_t)\Phi_n(n_t(\omega^t))} \left[+ \frac{1}{\mu_t} \sum_{\omega^{t+1}|\omega^t} \gamma_{t+1}(\omega^{t+1})\pi(\omega_{t+1}, \omega_t) \right].$$

By first-order condition with respect to $U_{t+1}(\omega^{t+1})$ and $c_t(\omega^t)$, we obtain the Euler equation as

$$u'(c_t(\omega^t)) = \frac{\mu_t}{\mu_{t+1}}\beta(\omega_t)u'(c_{t+1}(\omega^{t+1}))\frac{\Phi(n_t(\omega^t))}{n_t(\omega^t)}.$$

From this Euler equation, we can see that $c_{t+1}(\omega^{t+1})$ is independent of ω_{t+1} . Substitute it into

$$\begin{aligned} & E_t U_{t+1}(\omega^{t+1}) \\ &= \frac{\mu_t}{\mu_{t+1}}u'(c_{t+1}(\omega^{t+1}))\frac{\Phi(n_t(\omega^t))}{n_t(\omega^t)\Phi_n(n_t(\omega^t))} \left[+ \frac{1}{\mu_t} \sum_{\omega^{t+1}|\omega^t} \gamma_{t+1}(\omega^{t+1})\pi(\omega_{t+1}, \omega_t) \right]. \end{aligned}$$

Express the utility function of an individual with type history ω^t as

$$\begin{aligned} & U_t(\omega^t) \\ &= u(c_t(\omega^t)) + \frac{\Phi(n_t(\omega^t))u'(c_t(\omega^t))}{\Phi_n(n_t(\omega^t))n_t(\omega^t)} \left[F_2(K, L_t; A)l(\omega_t) + \frac{1}{\mu_t}\gamma_t(\omega^t) - c_t(\omega^t) \right]. \end{aligned}$$

Forward by one period and take expectation:

$$\begin{aligned}
 & E_t U_{t+1}(\omega^{t+1}) \\
 &= u(c_{t+1}(\omega^{t+1})) \\
 &+ u'(c_{t+1}(\omega^{t+1})) E_t \left[\frac{\Phi(n_{t+1}(\omega^{t+1}))}{\Phi_n(n_{t+1}(\omega^{t+1}))n_{t+1}(\omega^{t+1})} \left[\frac{F_2(K, L_{t+1}; A)l(\omega_{t+1})}{\mu_{t+1}} - c_{t+1}(\omega^{t+1}) \right] \right].
 \end{aligned}$$

Equating the two expressions of $E_t U_{t+1}(\omega^{t+1})$, and using the assumptions of the utility and altruism functions, $\frac{n_t(\omega^t)\Phi_n(n_t(\omega^t))}{\Phi(n_t(\omega^t))} = \psi$ and $\frac{u'(c_{t+1}(\omega^{t+1}))c_{t+1}(\omega^{t+1})}{u(c_{t+1}(\omega^{t+1}))} = \xi$, we can solve consumption as

$$c_{t+1}(\omega^{t+1}) = \frac{\xi}{\psi - \xi} \left[\frac{\mu_t}{\mu_{t+1}} [\eta(\omega_t) + F_2(K, L_t; A)l(\omega_t)\lambda_t(\omega_t)] - F_2(K, L_{t+1}; A)E_t[l(\omega_{t+1})|\omega_t] \right]$$

for all $t \geq 0$. Equation (56) and the resource constraint at time 0 determine $\{c_0(\omega_0)\}_{\omega_0 \in \Omega_0}$. Next let us derive the transversality condition regarding population. Assume the last period is T . The derivative of the Lagrangian to the last period fertility $n_T(\omega^T)$ is

$$-\mu_T N_T(\omega^T) (\eta(\omega_T) + F_2(K, L_T; A)l(\omega_T)\lambda_T(\omega_T)).$$

Iterate first-order condition with respect to $N_{T+1}(\omega^{T+1})$ and forward by one period:

$$\begin{aligned}
 \theta_t(\omega^t) &= \theta_{t-1}(\omega^{t-1}) \beta \frac{\Phi(n_{t-1}(\omega^{t-1}))}{n_{t-1}(\omega^{t-1})} = \dots \\
 &= \beta^t \theta_0(\omega^0) \left(\frac{N_t(\omega^t)}{N_0(\omega^0)\pi(\omega^t, \omega^0)} \right)^{\psi-1}.
 \end{aligned}$$

Then substitute it into the first-order condition with respect to $c_t(\omega^t)$:

$$\mu_t = \varphi_0(\omega^0) \left(\frac{N_t(\omega^t)}{N_0(\omega^0)\pi(\omega^t, \omega^0)} \right)^{\psi-1} \beta^t c_t(\omega^t)^{\xi-1}.$$

The condition becomes

$$\lim_{T \rightarrow \infty} \frac{\beta^T c_T(\omega^T)^{\xi-1} N_T(\omega^T)^{\psi}}{\pi(\omega^T, \omega^0)^{\psi-1}} (\eta(\omega_T) + F_2(K, L_T; A)l(\omega_T)\lambda_T(\omega_T)) = 0. \quad \square$$

PROOF OF LEMMA 5. At steady state, (36) becomes (37). Equation (38) can be obtained using (35) and the specified functional forms. The law of motion of population (8) becomes (39). Total population is constant and, therefore, average fertility is equal to 1 as stated by (40). Equations (41) and (42) are steady state versions of (9) and (7). \square

PROOF OF PROPOSITION 9. The proof is similar to that of Proposition 4. For the first part of the proposition, A is given, and $n(\omega_{-1}, \omega)$, $g(\omega_{-1}, \omega)$, Q , K/L , L/N , $c(\omega)$, and marginal product of labor (MPL) are solved by (38), (39), (40), (41), and (42),

$$c(\omega) = \frac{\xi Q}{\psi - \xi} [\eta(\omega) + \text{MPL} \cdot (l(\omega)\lambda(\omega) - E[l(\omega_{+1})|\omega]/Q)]$$

and

$$\text{MPL} = \left(1 - \alpha \left(\frac{K}{L}, A\right)\right) F\left(\frac{K}{L}, 1; A\right).$$

A change of land is adjusted only by population and labor. The proof of the second part follows the same way as in Proposition 4 and, hence, is omitted. \square

PROOF OF PROPOSITION 10. Recall that $\xi \equiv \frac{u'(c_{t+1}(\omega^{t+1}))c_{t+1}(\omega^{t+1})}{u(c_{t+1}(\omega^{t+1}))}$ and $\psi \equiv \frac{n_t(\omega^t)\Phi'(n_t(\omega^t))}{\Phi(n_t(\omega^t))}$. Use (44) to solve for $c_t(\omega^t)$ and plug it into initial parent's objective function (43). Then take first-order conditions:

$$\begin{aligned} k_t(\omega^t) &: \beta^{t-1} \prod_{j=0}^{t-2} \Phi(n_j(\omega^j)) u'(c_{t-1}(\omega^{t-1})) n_{t-1}(\omega^{t-1}) q_{t-1}(\omega_t, \omega_{t-1}) \\ &= \beta^t \prod_{j=0}^{t-1} \Phi(n_j(\omega^j)) u'(c_t(\omega^t)) \pi(\omega_t, \omega_{t-1})(r_t + p_t) \end{aligned}$$

for all $t > 0$. Simplifying to

$$u'(c_{t-1}(\omega^{t-1})) = \beta \frac{\Phi(n_{t-1}(\omega^{t-1}))}{n_{t-1}(\omega^{t-1})} u'(c_t(\omega^t)) \frac{r_t + p_t}{p_{t-1}} \quad \text{for all } t > 0, \tag{57}$$

so $c_{t+1}(\omega^{t+1})$ depends on ω^t but not on ω_{t+1} for all $t \geq 0$, it can be written as (46).

$$\begin{aligned} n_t(\omega^t) &: \beta^t \prod_{j=0}^{t-1} \Phi(n_j(\omega^j)) u'(c_t(\omega^t)) \left[\begin{array}{c} \eta(\omega_t) + \sum_{\omega_{t+1}} q_t(\omega_{t+1}, \omega_t) k_{t+1}(\omega^{t+1}) \\ + w_t(\omega_t)\lambda(\omega_t) \end{array} \right] \\ &= E_t \sum_{m=t+1}^{\infty} \beta^m \prod_{j=0}^{m-1} \Phi(n_j(\omega^j)) u(c_m(\omega^m)) \frac{\Phi'(n_t(\omega^t))}{\Phi(n_t(\omega^t))} \end{aligned}$$

for all $t \geq 0$. Cancel out $\beta^t \prod_{j=0}^{t-1} \Phi(n_j(\omega^j))$,

$$\begin{aligned} &u'(c_t(\omega^t)) \left[\eta(\omega_t) + \sum_{\omega_{t+1}} q_t(\omega_{t+1}, \omega_t) k_{t+1}(\omega^{t+1}) + w_t(\omega_t)\lambda(\omega_t) \right] \\ &= \Phi'(n_t(\omega^t)) E_t \sum_{m=t+1}^{\infty} \beta^{m-t} \prod_{j=t+1}^{m-1} \Phi(n_j(\omega^j)) u(c_m(\omega^m)), \end{aligned}$$

where $\prod_{j=t+1}^t \Phi(n_j(\omega^j)) = 1$. Use the first-order condition with respect to $k_{t+1}(\omega^{t+1})$ and forward by one period to substitute out $u'(c_t(\omega^t))$,

$$\begin{aligned} & \beta \frac{\Phi(n_t(\omega^t)) u'(c_{t+1}(\omega^{t+1}))}{n_t(\omega^t)} \frac{r_{t+1} + p_{t+1}}{p_t} \left[\begin{aligned} & \eta(\omega_t) + \sum_{\omega_{t+1}} q_t(\omega_{t+1}, \omega_t) k_{t+1}(\omega^{t+1}) \\ & + w_t(\omega_t) \lambda(\omega_t) \end{aligned} \right] \\ & = \Phi'(n_t(\omega^t)) E_t \sum_{m=t+1}^{\infty} \beta^{m-t} \prod_{j=t+1}^{m-1} \Phi(n_j(\omega^j)) u(c_m(\omega^m)), \end{aligned} \tag{58}$$

where

$$\begin{aligned} & E_t \sum_{m=t+1}^{\infty} \beta^{m-t-1} \prod_{j=t+1}^{m-1} \Phi(n_j(\omega^j)) u(c_m(\omega^m)) \\ & = E_t \left[u(c_{t+1}(\omega^{t+1})) + \Phi(n_{t+1}(\omega^{t+1})) \sum_{m=t+2}^{\infty} \beta^{m-t-1} \prod_{j=t+2}^{m-1} \Phi(n_j(\omega^j)) u(c_m(\omega^m)) \right]. \end{aligned} \tag{59}$$

Forward (58) by one period:

$$\begin{aligned} & \frac{\Phi(n_{t+1}(\omega^{t+1}))}{n_{t+1}(\omega^{t+1})} u'(c_{t+2}(\omega^{t+2})) \frac{r_{t+2} + p_{t+2}}{p_{t+1}} \left[\begin{aligned} & \eta(\omega_{t+1}) \\ & + \sum_{\omega_{t+2}} q_{t+1}(\omega_{t+2}, \omega_{t+1}) k_{t+2}(\omega^{t+2}) \\ & + w_{t+1}(\omega_{t+1}) \lambda(\omega_{t+1}) \end{aligned} \right] \\ & = \Phi'(n_{t+1}(\omega^{t+1})) E_{t+1} \sum_{m=t+2}^{\infty} \beta^{m-t-1} \prod_{j=t+2}^{m-1} \Phi(n_j(\omega^j)) u(c_m(\omega^m)) \quad \text{for } t \geq 0. \end{aligned} \tag{60}$$

By (57), (58), (59), (60), and the $(t + 1)$ -period budget constraint, we have

$$\begin{aligned} & u'(c_{t+1}(\omega^{t+1})) \frac{r_{t+1} + p_{t+1}}{p_t} \left[\eta(\omega_t) + \sum_{\omega_{t+1}} q_t(\omega_{t+1}, \omega_t) k_{t+1}(\omega^{t+1}) + w_t(\omega_t) \lambda(\omega_t) \right] \\ & = \psi u(c_{t+1}(\omega^{t+1})) + u'(c_{t+1}(\omega^{t+1})) E_t \left[\begin{aligned} & w_{t+1}(\omega_{t+1}) + (r_{t+1} + p_{t+1}) k_{t+1}(\omega^{t+1}) \\ & - c_{t+1}(\omega^{t+1}) \end{aligned} \right]. \end{aligned}$$

By the actuarially fair price of $q(\omega_{t+1}, \omega_t)$, we are able to cancel the term associated with

$$E_t [(r_{t+1} + p_{t+1}) k_{t+1}(\omega^{t+1})]$$

and solve $c_{t+1}(\omega^{t+1})$ as in (45) for all $t \geq 0$. The term $n_t(\omega^t)$ is given by (46), where $n_0(\omega_{-1}, \omega_0) = n_0(\omega_0)$. Notice that $c_{t+1}(\omega^{t+1})$ depends on ω_t for all t , and, hence, $n_t(\omega^t)$ depends on ω_t and ω_{t-1} for $t \geq 1$, while $n_0(\omega^0)$ depends on ω_0 . Given prices $\{w_t(\omega^t)\}_{t=0, \omega^t \in \Omega_t}^{\infty}$, $\{r_t\}_{t=0}^{\infty}$, $\{k_0(\omega^0)\}_{\omega^0 \in \Omega}$, and $\{N_0(\omega^0)\}_{\omega^0 \in \Omega}$, in equilibrium

$$\{c_0(\omega^0)\}_{\omega^0 \in \Omega}, \{c_{t+1}(\omega^{t+1})\}_{t=0, \omega^{t+1} \in \Omega_{t+1}}^{\infty}, \{n_t(\omega^t)\}_{t=0, \omega_{t-1}, \omega^t \in \Omega_t}^{\infty}, \{k_t(\omega^t)\}_{t=1, \omega^t \in \Omega_t}^{\infty},$$

$\{N_{t+1}(\omega^{t+1})\}_{t=0, \omega^{t+1} \in \Omega_{t+1}}^\infty$, and $\{L_t\}_{t=0}^\infty$ are solved by the system of equations consisting of (45), (46), (44), (8), and (7), where $n_0(\omega_{-1}, \omega_0) = n_0(\omega_0)$. Next let us derive the transversality condition associated with population. Assume the last period is T . The derivative of the objective with respect to $n_T(\omega^T)$ is

$$\begin{aligned} & - \lim_{T \rightarrow \infty} \beta^T \prod_{j=0}^{T-1} \Phi(n_j(\omega^j)) c_T(\omega^T)^{\xi-1} (w_T(\omega_T) \lambda(\omega_T) + \eta(\omega_T)) \pi(\omega^T, \omega_0) \\ & = - \lim_{T \rightarrow \infty} \beta^T \left(\frac{N_T(\omega^T)}{N_0(\omega^0)} \right)^\psi \frac{c_T(\omega^T)^{\xi-1}}{\pi(\omega^T, \omega_0)^{\psi-1}} (F_2(K, L_T; A) l_T(\omega_T) \lambda(\omega_T) + \eta(\omega_T)), \end{aligned}$$

so the condition becomes

$$\lim_{T \rightarrow \infty} \beta^T \frac{N_T(\omega^T)^\psi c_T(\omega^T)^{\xi-1}}{\pi(\omega^T, \omega_0)^{\psi-1}} (F_2(K, L_T; A) l_T(\omega_T) \lambda(\omega_T) + \eta(\omega_T)) = 0.$$

When the no-Ponzi game condition holds, we can use (44) to express the present value budget constraint. The condition is

$$\lim_{T \rightarrow \infty} \sum_{\omega^T | \omega_0} \frac{\prod_{j=0}^{T-2} q_j(\omega_{j+1}, \omega_j) n_j(\omega^j)}{\prod_{j=1}^{T-1} (r_j + p_j)} q_{T-1}(\omega_T, \omega_{T-1}) n_{T-1}(\omega^{T-1}) k_T(\omega^T) = 0.$$

Since

$$\begin{aligned} & \frac{\prod_{j=0}^{T-2} q_j(\omega_{j+1}, \omega_j) n_j(\omega^j)}{\prod_{j=1}^{T-1} (r_j + p_j)} \\ & = \beta^{T-1} \frac{N_{T-1}(\omega^{T-1})^\psi}{N_0(\omega^0)^\psi \pi(\omega^{T-1}, \omega_0)^\psi} \frac{u'(c_{T-1}(\omega^{T-1}))}{u'(c_0(\omega^0))} \pi(\omega^{T-1}, \omega_0), \end{aligned}$$

the no-Ponzi game condition can be written as

$$\begin{aligned} & \lim_{T \rightarrow \infty} \sum_{\omega^T | \omega_0} \beta^{T-1} \frac{N_{T-1}(\omega^{T-1})^{\psi-1}}{N_0(\omega^0)^\psi \pi(\omega^{T-1}, \omega_0)^{\psi-1}} \frac{u'(c_{T-1}(\omega^{T-1}))}{u'(c_0(\omega^0))} p_{T-1} N_T(\omega^T) k_T(\omega^T) \\ & = 0. \end{aligned} \quad \square$$

PROOF OF PROPOSITION 11. Substituting the allocation of the competitive equilibrium into (56) and picking an $\tilde{\omega}_0$ to normalize $\varphi_0(\tilde{\omega}_0) = 1$, we can solve for $\varphi_0(\omega_0)$ for all $\omega_0 \in \Omega$. Under this set of planner's weight, we can show that the competitive equilibrium allocation $\{c_t^c(\omega^t), n_t^c(\omega^t)\}_{\omega^t \in \Omega_t}$ and $\{\frac{\mu_{t+1}}{\mu_t}\}_{t=0}^\infty$ chosen as follows solves the social planner's problem. For a given series of dynasty history $\{\omega^t\}_{t \geq 0}$, set

$$\frac{\mu_{t+1}}{\mu_t} = \frac{1}{\psi} \beta(\omega_t) \Phi'(n_t^c(\omega^t)) \frac{u'(c_{t+1}^c(\omega^{t+1}))}{u'(c_t^c(\omega^t))}.$$

According to the Euler equation (46), $\mu_{t+1}/\mu_t = p_t/(p_{t+1} + r_{t+1})$. Because (46) holds for all $\{\omega^t\}_{t \geq 0}$, this holds for all $\{\omega^t\}_{t \geq 0}$. By the consumption formula of the competitive equilibrium (45), the condition for consumption of the planner's problem, (36), is satisfied. Summing up the budget constraints multiplied by population of every type history, using the equilibrium condition for land,

$$K = \sum_{\omega^t \in \Omega_t} N_t^c(\omega^t) k_t^c(\omega^t),$$

and using the homogeneity of the production function, the resource constraint

$$F(K, L_t; A) = \sum_{\omega^t} N_t(\omega^t) [c_t(\omega^t) + \eta(\omega_t) n_t(\omega^t)]$$

is satisfied. By the construction of $\varphi_0(\omega_0)$, the condition (56) that characterizes the relative magnitude of the initial consumptions in the planner problem is satisfied. The Euler equation of the planner's problem (35) is satisfied by the proposed value of μ_{t+1}/μ_t . The equations that characterize the evolution of population, the labor supply, and the transversality condition are all the same in the two problems. Hence, the competitive equilibrium allocation $\{c_t(\omega^t), n_t(\omega^t)\}_{\omega^t \in \Omega_t}$ and the ratio of the Lagrangian multipliers $\{\frac{\mu_{t+1}}{\mu_t}\}_{t=0}^\infty$ set above solve the social planner's problem under the chosen set of $\{\varphi_0(\omega_0)\}_{\omega_0 \in \Omega}$. \square

PROOF OF PROPOSITION 12. Let $\{c_t^P(\omega^t), n_t^P(\omega^t)\}_{t=0}^\infty$ be the solution of the social planner's problem that maximizes SW_2 . We set up the price system as follows. Fix a dynasty with its history $\{\omega^t\}_{t \geq 0}$,

$$p_{t+1} = p_t \frac{1}{\beta} \frac{n_t^P(\omega^t)}{\Phi(n_t^P(\omega^t))} \frac{u'(c_t^P(\omega^t))}{u'(c_{t+1}^P(\omega^{t+1}))} - r_{t+1}$$

$$p_0 = \sum_{t=0}^\infty \beta^{t+1} \left(\prod_{j=0}^t \frac{\Phi(n_j^P(\omega^j))}{n_j^P(\omega^j)} \right) \frac{u'(c_{t+1}^P(\omega^{t+1}))}{u'(c_0^P(\omega^0))} r_{t+1}$$

$$q_t(\omega_{t+1}, \omega_t) = p_t \pi(\omega_{t+1}, \omega_t)$$

$$r_t = F_K(K, L^P; A)$$

$$w_t(\omega_t) = F_L(K, L^P; A) l(\omega_t).$$

The terms L_t^P and $N_{t+1}^P(\omega^{t+1})$ are determined by (7) and (8), while fertilities are $\{n_t^P(\omega^t)\}_{t=0}^\infty$. Under this set of price and the social planner's allocations, we can solve for $\{k_0(\omega_0)\}_{\omega_0 \in \Omega_0}$ using the present value of the resource constraint

$$\sum_{t=0}^\infty \sum_{\omega^t | \omega_0} \frac{\prod_{j=0}^{t-1} n_j^P(\omega^j) q_j(\omega_{j+1}, \omega_j)}{\prod_{j=0}^{t-1} (r_{j+1} + p_{j+1})} (c_t^P(\omega^t) + \eta(\omega_t) n_t^P(\omega^t))$$

$$\begin{aligned} &\leq (r_0 + p_0)k_0(\omega^0) \\ &+ \sum_{t=0}^{\infty} \sum_{\omega^t|\omega_0} \frac{\prod_{j=0}^{t-1} n_j^P(\omega^j)q_j(\omega_{j+1}, \omega_j)}{\prod_{j=0}^{t-1} (r_{j+1} + p_{j+1})} w_t(\omega_t)(1 - \lambda(\omega_t)n_t^P(\omega^t)). \end{aligned}$$

Allocation $\{k_{t+1}(\omega^{t+1})\}_{\omega^{t+1} \in \Omega_{t+1}, t \geq 0}$ is solved by (44). Under the initial capital allocation $\{k_0(\omega_0)\}_{\omega_0 \in \Omega_0}$ solved above, we can show that the allocations of the social planner's problem satisfy all the equations that characterize competitive equilibrium in Proposition 10. The set of prices constructed implies that the return to land in the competitive equilibrium is equal to the ratio of the resource across periods in the planner's problem, that is, $(r_{t+1} + p_{t+1})/p_t = \mu_t/\mu_{t+1}$. This equality and the consumption formulation of the planner's problem lead to (45). Since the Euler equation (35) of the planner's problem holds for all $\omega^t \in \Omega_t$ and all $t \geq 0$, (46) is satisfied by the construction of prices for all $\omega^t \in \Omega_t$ and $t \geq 0$. Budget constraints are satisfied because capital allocations $\{k_{t+1}(\omega^{t+1})\}_{\omega^{t+1} \in \Omega_{t+1}, t \geq 0}$ are chosen based on them. The transversality conditions of the two problems coincide. The way we pick $\{k_0(\omega_0)\}_{\omega_0 \in \Omega_0}$ and $\{k_{t+1}(\omega^{t+1})\}_{\omega^{t+1} \in \Omega_{t+1}, t \geq 0}$ guarantees the no-Ponzi game. The planner's allocation satisfies the resource constraints. Summing up the budget constraints among different ω^t in every period and using the resource constraint, we obtain

$$K = \sum_{\omega^t \in \Omega_t} N_t^P(\omega^t)k_t(\omega^t) \quad \text{for all } \omega^t \in \Omega_t \text{ and } t \geq 0.$$

The prices constructed above are those in competitive equilibrium. The initial land distribution $\{k_0(\omega_0)\}_{\omega_0 \in \Omega_0}$ decentralizes the social planner's problem with given weights $\{\varphi_0(\omega_0)\}_{\omega_0 \in \Omega}$. □

A.2 Deterministic case with one type

A.2.1 *The case* $\varphi_t = \delta^t$ and $\delta \geq \beta$.

PROPOSITION 13. Assume $\eta > 0$. (i) If $\delta > \beta$, a steady state satisfies

$$\begin{aligned} c = & \frac{\xi(c)\eta \left(\frac{\alpha\delta}{1-\delta} - \frac{(1-\alpha)\lambda}{1-\lambda} - 1 \right)}{\frac{\delta-\beta}{(1-\beta)(1-\delta)} - \frac{\beta\Phi'(1)}{1-\beta} - \xi(c) \left(\frac{\alpha\delta}{\delta-1} - \frac{(1-\alpha)\lambda}{1-\lambda} \right)} \\ & F\left(\frac{K}{N}, 1-\lambda; A\right) = c + \eta \end{aligned} \tag{61}$$

and

$$\frac{\theta_{t+1}}{\theta_t} = \frac{\mu_{t+1}}{\mu_t} = \frac{\gamma_{t+1}}{\gamma_t} = \delta.$$

In this case, the Malthusian stagnation property holds. (ii) If $\delta = \beta$, the steady state does not exist.

PROOF. (i) When $\eta > 0$ and N is finite, we can first show that $\theta_{t+1}/\theta_t = \delta$. Otherwise, if $\theta_{t+1}/\theta_t > \delta$, then in the limit, according to (21),

$$\theta_{t+1}/\theta_t = \beta + \frac{\delta^{t+1}}{\theta_t}. \tag{62}$$

Then $\theta_{t+1}/\theta_t = \beta < \delta$, a contradiction. If $\theta_{t+1}/\theta_t < \delta$, then the right-hand side of (62) explodes, which also leads to a contradiction. Equation (17) then implies that the growth rate of μ_t is the same as that of θ_t , which is δ . Furthermore, (22) at steady state simplifies to

$$U - \frac{\mu_{t+1}}{\delta^{t+1}} F_K \frac{K}{N} = \frac{\gamma_{t+1}}{\delta^{t+1}} \left(\frac{\gamma_{t+2}}{\gamma_{t+1}} - 1 \right).$$

The left-hand side of this equality is constant in steady state since the growth rate of μ is δ . Then for the right-hand side to converge to a constant, we have three possibilities: γ_t grows at a rate smaller than δ , γ_t grows at the rate δ , and γ_t keeps constant over time, e.g., $\gamma_{t+2}/\gamma_{t+1} = 1$.

Consider the first possibility when γ_t grows at a rate smaller than δ . Then

$$U = \frac{\mu_{t+1}}{\delta^{t+1}} F_K \frac{K}{N}. \tag{63}$$

Express (21) and (17) at steady state:

$$\begin{aligned} \theta_t &= \frac{\delta^{t+1}}{\delta - \beta} \\ \mu_t = \theta_t u'(c) &= \frac{\delta^{t+1}}{\delta - \beta} u'(c). \end{aligned} \tag{64}$$

Plug it into (63) and use $U = u(c)/(1 - \beta)$ at steady state:

$$c = \frac{\delta(1 - \beta)}{\delta - \beta} \xi(c) F_K \frac{K}{N}.$$

By the constant returns to scale assumption and the definition of α above, it can be written as

$$\frac{c}{\xi(c)} = \frac{\delta(1 - \beta)}{\delta - \beta} \alpha \frac{F(K, L; A)}{N}, \tag{65}$$

which together with (61) and $L = N(1 - \lambda)$ can be used to solve (c, N) . Given that the growth rate of γ_t is less than that of μ_t according to (64), we express (23) at steady state as

$$\beta \Phi'(1) \frac{c}{\xi(c)} \frac{1}{1 - \beta} = \eta + (1 - \alpha) \frac{F(K, L; A)}{N} \frac{\lambda}{1 - \lambda}. \tag{66}$$

Using $\Phi'(1) = \psi$ and (61), we solve consumption as

$$c = \frac{\xi(c) \frac{1-\beta}{\beta\psi} \left[1 + (1-\alpha) \frac{\lambda}{1-\lambda} \right] \eta}{1 - \xi(c) \frac{1-\beta}{\beta\psi} (1-\alpha) \frac{\lambda}{1-\lambda}}.$$

The (c, N) solved from (65) and (61) does not satisfy (66) in general. Therefore, in the case of δ larger than β , the steady state with each multiplier growing at a constant rate, in particular, γ_t growing at a constant rate smaller than δ , is not the optimal solution except for a knife-edge condition in which (c, N) satisfies (61), (65), and (66) simultaneously.

Next consider the second possibility when γ_t grows at the rate of δ . Express (21), (23), and (17) at steady state, respectively, as

$$\theta_t = \frac{\delta^{t+1}}{\delta - \beta} \tag{67}$$

$$\gamma_t = \frac{1}{\delta} \mu_t \left[\beta \Phi'(1) \frac{U}{u'(c)} - \eta - F_L \lambda \right] \tag{68}$$

and

$$\mu_t = \theta_t u'(c) = \frac{\delta^{t+1}}{\delta - \beta} u'(c). \tag{69}$$

Plugging (68) into the steady state formula of (22), we get

$$\frac{\delta^{t+1}}{\gamma_{t+1}} U = \frac{\delta}{\beta \Phi'(1) \frac{U}{u'(c)} - \eta - F_L \lambda} F_K \frac{K}{N} + \delta - 1.$$

Using (67), (68), and (69), we get

$$(\delta - \beta)U = \delta u'(c) F_K \frac{K}{N} + \frac{\delta - 1}{\delta} \frac{\mu_{t+1}}{\mu_t} u'(c) \left[\beta \Phi'(1) \frac{U}{u'(c)} - \eta - F_L \lambda \right].$$

Having shown that μ_t grows at the rate δ , then

$$\frac{1}{1 - \beta} = \frac{\delta - 1}{\delta - \beta} \frac{\xi(c)}{c} \left[\beta \Phi'(1) \frac{U}{u'(c)} - \eta - F_L \lambda + \frac{\delta}{\delta - 1} F_K \frac{K}{N} \right].$$

Note that

$$F_L = \left(\frac{1 - \alpha}{1 - \lambda} \right) \frac{F}{N}$$

$$F_K \frac{K}{N} = \alpha \frac{F}{N}.$$

So the above equality becomes

$$\frac{\delta - \beta}{(1 - \beta)(\delta - 1)} = \frac{\xi(c)}{c} \left[\begin{array}{c} \beta\Phi'(1)c \frac{1}{\xi(c)} \frac{1}{1 - \beta} - \eta \\ + F\left(\frac{K}{N}, 1 - \lambda; A\right) \left(\frac{\alpha\delta}{\delta - 1} - \frac{(1 - \alpha)\lambda}{1 - \lambda} \right) \end{array} \right],$$

which together with (61) solves (c, N) . Substituting N out, we get

$$c = \frac{\xi(c)\eta \left(\frac{\alpha\delta}{1 - \delta} - \frac{(1 - \alpha)\lambda}{1 - \lambda} - 1 \right)}{\frac{\delta - \beta}{(1 - \beta)(1 - \delta)} - \frac{\beta\Phi'(1)}{1 - \beta} - \xi(c) \left(\frac{\alpha\delta}{\delta - 1} - \frac{(1 - \alpha)\lambda}{1 - \lambda} \right)}.$$

This formula of consumption implies the Malthusian stagnation property.

For the third possibility, $\gamma_{t+1}/\gamma_t = 1$ at steady state, which together with $\mu_{t+1}/\mu_t = \delta < 1$ contradicts (23).

(ii) If $\delta = \beta$, (21) becomes

$$\frac{\theta_{t+1}}{\theta_t} = \frac{\beta^{t+1}}{\theta_t} + \beta \geq \beta.$$

If $\lim_{t \rightarrow \infty} \theta_{t+1}/\theta_t = \beta$, then $\lim_{t \rightarrow \infty} \beta^{t+1}/\theta_t > 0$ and θ_{t+1}/θ_t converges to a number strictly greater than β , which leads to a contradiction. If $\lim_{t \rightarrow \infty} \theta_{t+1}/\theta_t > \beta$, then $\lim_{t \rightarrow \infty} \theta_{t+1}/\theta_t = \lim_{t \rightarrow \infty} \beta^{t+1}/\theta_t = 0$, a contradiction too. Hence, a steady state with Lagrangian multipliers growing at a constant rate over time does not exist in this case. \square

A.2.2 Stability of the steady state To get some insights about the stability of the steady state, in this section we also focus on the deterministic case with one type and assume $\varphi_0(\omega_0) = 1$ but $\varphi_{t+1}(\omega^{t+1}) = 0$ for all $t > 0$. In that case, the social planner cares about future generations to the extent that the initial generation does. Furthermore, assume no time costs of raising children, $\lambda = 0$, Barro and Becker’s functional forms $\Phi(n) = n^\psi$, $u(c) = c^\xi/\xi$, a Cobb–Douglas production function $F(K, N_t; A) = AK^\alpha N_t^{1-\alpha}$, and $N_0 = 1$. The restriction $\psi > \xi$ is required for concavity.

Initial parent’s utility is then given by

$$U_0 = u(c_0) + \beta n_0^\psi U_1 = \sum_{t=0}^{\infty} \beta^t \prod_{j=0}^{t-1} n_j^\psi u(c_t) = \sum_{t=0}^{\infty} \beta^t N_t^\psi \frac{1}{\xi} c_t^\xi.$$

The social planner’s problem is

$$\max_{\{C_t, N_{t+1}\}_{t=0}^{\infty}} \sum_{t=0}^{\infty} \beta^t N_t^\psi \frac{1}{\xi} c_t^\xi \quad \text{subject to } c_t N_t = F(K, L_t; A) - N_{t+1} \eta.$$

Substitute the budget constraint into the objective function:

$$\max_{\{C_t, N_{t+1}\}_{t=0}^{\infty}} \sum_{t=0}^{\infty} \beta^t N_t^\psi \frac{1}{\xi} \left(\frac{F(K, N_t; A) - N_{t+1} \eta}{N_t} \right)^\xi.$$

The optimal choice of population in period t is

$$N_t^{\psi-\xi} C_t^{\xi-1} \eta = \beta N_{t+1}^{\psi-\xi} C_{t+1}^{\xi-1} \left[\left(\frac{\psi}{\xi} - \alpha \right) AK^\alpha N_{t+1}^{-\alpha} - \eta \frac{\psi - \xi}{\xi} \frac{N_{t+2}}{N_{t+1}} \right],$$

where $C_t = c_t N_t$ is the aggregate consumption of all people of generation t . It is convenient to define the variable $X_t \equiv N_t^{\frac{\xi-\psi}{1-\xi}} C_t$, a mix between aggregate consumption and a factor that depends on population. Then the dynamic system can be described by

$$\begin{aligned} X_t &= N_t^{\frac{\xi-\psi}{1-\xi}} \left[AK^\alpha N_t^{1-\alpha} - N_{t+1} \eta \right] \\ \left(\frac{X_{t+1}}{X_t} \right)^{1-\xi} \eta &= \beta \left[\left(\frac{\psi}{\xi} - \alpha \right) AK^\alpha N_{t+1}^{-\alpha} - \eta \frac{\psi - \xi}{\xi} \frac{N_{t+2}}{N_{t+1}} \right]. \end{aligned}$$

The first equation is the resource constraint and the second is the optimality condition for population. Steady state population N^* can be solved as

$$AK^\alpha N^{*-\alpha} = \frac{\psi - \xi + \xi/\beta}{\psi - \alpha\xi} \eta.$$

Next we take a first-order Taylor expansion of this system around the steady state to analyze its stability. It is determined by the system of equations

$$W \begin{bmatrix} \frac{dN_{t+2}}{dX_{t+1}} \\ \frac{N^*}{X^*} \end{bmatrix} = G \begin{bmatrix} \frac{dN_{t+1}}{dX_t} \\ \frac{N^*}{X^*} \end{bmatrix}, \tag{70}$$

where

$$W = \begin{bmatrix} \eta \frac{N^{*(1-\psi)/(1-\xi)}}{\beta \frac{\psi - \xi}{\xi}} & 1 \\ \beta \frac{\psi - \xi}{\xi} & 1 - \xi \end{bmatrix}$$

and

$$G = \begin{bmatrix} (\xi - \psi)/(1 - \xi) + (1 - \alpha) \left(1 + \eta \frac{N^{*(1-\psi)/(1-\xi)}}{X} \right) & 0 \\ (1 - \alpha) \beta \frac{\psi - \xi}{\xi} - \alpha & 1 - \xi \end{bmatrix}.$$

The following proposition provides the necessary and sufficient conditions under which the steady state is saddle-path stable.

PROPOSITION 14. *The necessary and sufficient conditions for saddle-path stability of the steady state are*

$$(2 - \alpha) \frac{\frac{\psi - \xi}{\xi} (1 - 2\xi + (1 - \alpha)\beta) + 2(1 - \alpha)(1 - \xi)}{1/\beta - (1 - \alpha)} > \alpha(1 - 2\xi) - 2(1 - \psi)$$

and

$$\frac{1}{\beta}(\alpha(1 - \xi) - 1 + \psi) \neq (1 - \alpha) \frac{\psi - \xi}{\xi}.$$

PROOF. Equation (70) can be written as

$$\begin{bmatrix} \frac{dN_{t+2}}{dX_{t+1}} \\ \frac{N^*}{X^*} \end{bmatrix} = D \begin{bmatrix} \frac{dN_{t+1}}{dX_t} \\ \frac{N^*}{X^*} \end{bmatrix},$$

where

$$D \equiv W^{-1}G$$

$$\begin{aligned} &= \begin{bmatrix} \eta \frac{N^{*(1-\psi)/(1-\xi)}}{\beta \frac{\psi - \xi}{\xi}} & 1 \\ & 1 - \xi \end{bmatrix}^{-1} \begin{bmatrix} \frac{\xi - \psi}{1 - \xi} + (1 - \alpha) \left(1 + \eta \frac{N^{*(1-\psi)/(1-\xi)}}{X^*} \right) & 0 \\ (1 - \alpha) \beta \frac{\psi - \xi}{\xi} - \alpha & 1 - \xi \end{bmatrix} \\ &= \frac{1}{d} \begin{bmatrix} \left(\xi - \psi + (1 - \xi)(1 - \alpha) \left(1 + \eta \frac{N^{*(1-\psi)/(1-\xi)}}{X^*} \right) \right) & \xi - 1 \\ + \alpha - (1 - \alpha) \beta \frac{\psi - \xi}{\xi} & \\ - \beta \frac{\psi - \xi}{\xi} \left((1 - \psi)/(1 - \xi) - \alpha \right) - \alpha \eta \frac{N^{*(1-\psi)/(1-\xi)}}{X^*} & \eta \frac{N^{*(1-\psi)/(1-\xi)}}{X^*} (1 - \xi) \end{bmatrix}, \end{aligned}$$

with $d = \eta \frac{N^{*(1-\psi)/(1-\xi)}}{X^*} (1 - \xi) - \beta \frac{\psi - \xi}{\xi}$. Let λ_1 and λ_2 denote the eigenvalues of the matrix D . Assume, without loss of generality, that $\lambda_1 > \lambda_2$. They are solved by

$$\begin{aligned} \lambda_1 &= \frac{\text{tr}(D) + \sqrt{\text{tr}(D)^2 - 4 \det(D)}}{2} \\ \lambda_2 &= \frac{\text{tr}(D) - \sqrt{\text{tr}(D)^2 - 4 \det(D)}}{2}, \end{aligned}$$

where $\det(D)$ and $\text{tr}(D)$ can be solved as

$$\begin{aligned} &d^2 \det(D) \\ &= \left\{ \begin{bmatrix} \left[\xi - \psi + (1 - \xi)(1 - \alpha) \left(1 + \eta \frac{N^{*(1-\psi)/(1-\xi)}}{X^*} \right) \right] \eta \frac{N^{*(1-\psi)/(1-\xi)}}{X^*} (1 - \xi) \\ + \alpha - (1 - \alpha) \beta \frac{\psi - \xi}{\xi} \\ - (1 - \xi) \left[\beta \frac{\psi - \xi}{\xi} \left((1 - \psi)/(1 - \xi) - \alpha \right) + \alpha \eta \frac{N^{*(1-\psi)/(1-\xi)}}{X^*} \right] \end{bmatrix} \right\} \\ &d \cdot \text{tr}(D) = \left\{ \begin{bmatrix} \xi - \psi + (1 - \xi)(1 - \alpha) \left(1 + \eta \frac{N^{*(1-\psi)/(1-\xi)}}{X^*} \right) + \alpha \\ - (1 - \alpha) \beta \frac{\psi - \xi}{\xi} + \eta \frac{N^{*(1-\psi)/(1-\xi)}}{X^*} (1 - \xi) \end{bmatrix} \right\}. \end{aligned}$$

For saddle-path stability, either $|\lambda_1| < 1$ and $|\lambda_2| > 1$ or $|\lambda_1| > 1$ and $|\lambda_2| < 1$. Since $\lambda_1 > \lambda_2$ by assumption, this condition can be divided into two cases: (i) $\lambda_1 > 1$ and $-1 < \lambda_2 <$

1, and (ii) $\lambda_2 < -1$ and $-1 < \lambda_1 < 1$. Let us first consider case (i), which can be reduced to $1 - \text{tr}(D) < -\det(D) < 1 + \text{tr}(D)$, and then to

$$(1 - D_{11})(1 - D_{22}) < D_{12}D_{21} < (1 + D_{11})(1 + D_{22}),$$

where D_{ij} refers to the (i, j) element of matrix D . The condition in case (ii) can be reduced to $\text{tr}(D) + 1 < -\det(D) < -\text{tr}(D) + 1$, and then to

$$(1 + D_{11})(1 + D_{22}) < D_{12}D_{21} < (1 - D_{11})(1 - D_{22}).$$

Now let us derive terms in these conditions:

$$d^2 D_{12}D_{21} = \left(-\beta \frac{\psi - \xi}{\xi} \left((1 - \psi)/(1 - \xi) - \alpha \right) - \alpha \eta \frac{N^{*(1-\psi)/(1-\xi)}}{X^*} \right) (\xi - 1)$$

$$d(1 - D_{11}) = \psi - (1 + \alpha\xi) + \alpha(1 - \xi)\eta \frac{N^{*(1-\psi)/(1-\xi)}}{X^*} - \alpha\beta \frac{\psi - \xi}{\xi}$$

$$d(1 - D_{22}) = -\beta \frac{\psi - \xi}{\xi}$$

$$d^2(1 - D_{11})(1 - D_{22}) = -\beta \frac{\psi - \xi}{\xi} \left(\psi - 1 - \alpha\xi + \alpha(1 - \xi)\eta \frac{N^{*(1-\psi)/(1-\xi)}}{X^*} - \alpha\beta \frac{\psi - \xi}{\xi} \right).$$

Using the above result, derive the condition $(1 - D_{11})(1 - D_{22}) < D_{12}D_{21}$ in case (i). It holds if and only if

$$\eta(1 - \xi) \frac{N^{*(1-\psi)/(1-\xi)}}{X^*} > \beta \frac{\psi - \xi}{\xi}. \tag{71}$$

At steady state,

$$\eta \frac{N^{*(1-\psi)/(1-\xi)}}{X^*} = \frac{\psi/\xi - \alpha}{1/\beta - (1 - \alpha)}. \tag{72}$$

Substituting $\frac{N^{*(1-\psi)/(1-\xi)}}{X^*}$ out using (72), it becomes

$$\begin{aligned} & \frac{1}{\beta}(-1 + \psi + \alpha(1 - \xi)) < \frac{\psi - \xi}{\xi}(1 - \alpha) \\ & d^2(1 + D_{11})(1 + D_{22}) \\ & = \left[(2 - \alpha)\eta \frac{N^{\frac{1-\psi}{1-\xi}}}{X} (1 - \xi) - (2 - \alpha)\beta \frac{\psi - \xi}{\xi} + 1 - \psi + \alpha\xi \right] \\ & \quad \times \left(2\eta \frac{N^{\frac{1-\psi}{1-\xi}}}{X} (1 - \xi) - \beta \frac{\psi - \xi}{\xi} \right), \end{aligned} \tag{73}$$

and $D_{12}D_{21} < (1 + D_{11})(1 + D_{22})$ holds if and only if

$$\begin{pmatrix} 2(2 - \alpha)\eta(1 - \xi) \frac{N^{*(1-\psi)/(1-\xi)}}{X^*} \\ -(2 - \alpha)\beta \frac{\psi - \xi}{\xi} + 2(1 - \psi) \\ + \alpha - 2\alpha(1 - \xi) \end{pmatrix} \begin{pmatrix} \eta(1 - \xi) \frac{N^{*(1-\psi)/(1-\xi)}}{X^*} \\ -\beta \frac{\psi - \xi}{\xi} \end{pmatrix} > 0.$$

When (71) holds true, this inequality holds if and only if

$$2(2 - \alpha)\eta(1 - \xi) \frac{N^{*(1-\psi)/(1-\xi)}}{X^*} - (2 - \alpha)\beta \frac{\psi - \xi}{\xi} > 2\alpha(1 - \xi) - 2(1 - \psi) - \alpha.$$

Substituting $\frac{N^{*(1-\psi)/(1-\xi)}}{X^*}$ out using (72) gives

$$(2 - \alpha) \frac{\frac{\psi - \xi}{\xi} (1 - 2\xi + (1 - \alpha)\beta) + 2(1 - \alpha)(1 - \xi)}{1/\beta - (1 - \alpha)} > \alpha(1 - 2\xi) - 2(1 - \psi). \tag{74}$$

Hence, the condition for case (i) is (73) and (74). In the same way, we can derive that the condition for case (ii) is

$$\frac{1}{\beta} (\alpha(1 - \xi) - 1 + \psi) > (1 - \alpha) \frac{\psi - \xi}{\xi}$$

and (74). To summarize case (i) and case (ii), the sufficient and necessary condition for saddle-path stability is (74) and

$$\frac{1}{\beta} (\alpha(1 - \xi) - 1 + \psi) \neq (1 - \alpha) \frac{\psi - \xi}{\xi}. \quad \square$$

Given $\xi < \psi$, the Barro–Becker assumption for the concavity of the problem, this condition holds for most sets of parameters. The other condition holds for a wide range of parameters. In particular, a nice sufficient condition guarantees that saddle-path stability is $\xi < \frac{1}{2}$ and $\alpha(1 - 2\xi) \leq 2(1 - \psi)$. We summarize this in the following corollary.

COROLLARY 2. *Sufficient conditions for saddle-path stability of the steady state are $\xi < \frac{1}{2}$ and $\alpha(1 - 2\xi) < 2(1 - \psi)$.*

Under these conditions, the left-hand side of the first condition in Proposition 14 is positive, while its right-hand side is negative.
