Abstract

Prominent research argues that consumers often use personal budgets to manage self-control problems. This paper analyzes the link between budgeting and self-control problems in consumption-saving decisions. It shows that the use of good-specific budgets depends on the combination of a demand for commitment and the demand for flexibility resulting from uncertainty about intratemporal trade-offs between goods. It explains the subtle mechanism which renders budgets useful commitments, their interaction with minimum-savings rules (another widely-studied form of commitment), and how budgeting depends on the intensity of self-control problems. This theory matches several empirical findings on personal budgeting.

JEL CLASSIFICATION: D23, D82, D86, D91, E62, G31

KEYWORDS: budget, minimum-savings rule, commitment, flexibility, intratemporal trade-off, uncertainty, present bias.
1 Introduction

Many studies argue that personal budgeting is a pervasive part of consumer behavior.\(^1\) This practice involves grouping expenses into categories and constraining each with an implicit or explicit cap applied to a specified time period (a week, a month, etc.).\(^2\) While this practice cannot be explained by the classic life-cycle theory of the consumer, it has important consequences. It can account for “mysterious” large differences in wealth accumulation between consumers, which time or risk preferences cannot explain (Ameriks John et al. (2003)). By violating the principle of fungibility of money, it shapes demand differently from satiation and income effects (Heath Chip and Soll Jack B. (1996)). It affects how firms promote their products so as to avoid competing for the same budget (Wertenbroch Klaus (2002)). It is at the foundation of the economics of commitment devices (Bryan Gharad et al. (2010)). Almost all existing studies informally suggest that consumers use budgets to manage self-control problems, often caused by present bias, which interfere with their saving goals (Thaler Richard H. (1999); Ameriks John et al. (2003); Antonides Gerrit et al. (2011)).

Despite this consensus, a formal investigation of the link between budgeting and self-control problems seems to be missing. The paper offers such a foundation using a broadly studied aspect of time preferences: present bias. It shows, however, that present bias alone cannot explain budgeting. Present-biased consumers value constraints on future choices. But for budgets to emerge, this preference for commitment has to be combined with a preference for flexibility of a precise but plausible kind, namely, that caused by uncertainty about intratemporal trade-offs—for instance, due to good-specific taste shocks. The paper also uncovers a tension between good-specific budgets and minimum-savings rules, an often-studied form of commitment. This leads to a negative relationship between the level of present bias and the use of budgets. These predictions help organize the evidence on budgeting and can guide future empirical studies.

Consider an agent, Ann, who has two selves: a time-consistent self-0 and a present-biased self-1.\(^3\) Both selves have the same per-period consumption utility. In each period, self-1 chooses consumption and savings subject to the usual income constraint. Suppose that (i) consumption involves multiple goods (not a single uniform commodity), and (ii) both selves’ preferences depend on a state of the world (capturing taste shocks) which affects not only the rate of substitution between present and future utility, but also the

---

\(^2\)This paper uses the term “personal budgeting” rather than “mental accounting” because the latter has the much broader meaning of a general process whereby people frame events, outcomes, and decisions. This also includes choice bracketing, narrow framing, and gain-loss utility, which differ from budgeting.

rates of substitution between goods within periods. In each period, before the state realizes, Ann’s self-0 can adopt a commitment plan dictating which income allocations self-1 is allowed to choose. This creates a trade-off between commitment and flexibility. The paper focuses on plans that can freely combine good-specific budgets and an overall limit on consumption expenses via a savings floor. This is in line with its motivation and offers an interesting lower bound on self-0’s payoff. Of course, one would want to allow for general forms of commitment, which is however much harder in the presence of feature (i) and (ii) (see Section 4) and is beyond the scope of the paper.\footnote{This paper takes the process of noticing an expense and reporting it to its budget as a defining aspect of budgeting itself. To focus on the issues of interest here, it also assumes that people stick to their commitment plans, as justified in Section 2.}

Feature (i) and (ii) are the key differences between this paper and Amador Manuel et al. (2006), where consumption involves a single commodity and taste shocks affect only the intertemporal utility trade-off. That paper shows that, under very general conditions on the shock distribution, the optimal rule is to impose a saving floor and grant self-1 flexibility otherwise—even if self-0 can choose among arbitrarily general forms of commitment. To establish a benchmark, Section 3.2 shows that their result carries over to a world with multiple goods if there is no uncertainty about intratemporal trade-offs between goods. Intuitively, in this case binding good-specific budgets force self-1 to choose inefficient consumption bundles, which is akin to wasting resources (i.e., “money burning”). But Amador Manuel et al. (2006) already showed that money burning is generally suboptimal.

Uncertain intratemporal trade-offs change things substantially, as summarized by the main results of the paper. First, if the goods satisfy appropriate substitutability and normality conditions, optimal commitment plans always involve good-specific budgets when present bias is sufficiently \textit{weak}, but only a savings floor when present bias is sufficiently \textit{strong}. Second, fixing a weak bias, for some range of parameters the optimal plans combine budgets with a savings floor, but for another range they rely only on the budgets. By contrast, in Amador Manuel et al. (2006) optimal plans \textit{always} involve a savings floor.\footnote{These properties continues to hold for partially naive agents who incorrectly anticipate their bias.} The substitutability and normality conditions ensure that the consumption distortions caused by budgets curtail how much self-1 gains in terms of present utility by undersaving, thereby resulting in higher savings. This improvement matters more than those distortions for the time-consistent self-0.

To see the intuition for these results, suppose Ann consumes two goods and is uncertain whether her marginal utility of each good will be high or low. Anticipating her tendency to undersave, she first considers setting a savings floor. This will limit overspending if both marginal utilities are high, which make her want to consume a lot of both goods. If only one marginal utility turns out to be high, however, the floor may not bind; and this is especially likely if present bias is weak. In this case, Ann realizes that she will still overspend and this will be mostly driven by the good with high marginal utility. She can then also cap this good with a targeted budget, which raises her savings because now she can overspend only on the good with low marginal utility. On the other hand, when present bias is stronger, overspending becomes more severe even for the good...
with low marginal utility, and the budget leads to a small (if any) rise in savings at the cost of rationing a good with high marginal utility. As a result, Ann prefers to adopt only a savings floor, for it curbs undersaving without distorting consumption.

The results involve some noteworthy subtleties. An agent may adopt budgets, which distort consumption spending, even though her selves always agree on how to divide every dollar between goods within a period. By contrast, a binding floor distorts only the income division between spending and saving. Perhaps counterintuitively, it is not the case that if a present-biased agent adds budgets to a floor, then a more biased agent should do the same. In addition, agents who use budgets may also set tighter floors, as the budgets’ distortions lower the value of leaving more income for consumption. Once budgets are allowed, agents with a stronger present bias may adopt a slacker floor (in contrast to Proposition 5 in Amador Manuel et al. (2006)). Section 3 further discusses the results in relation to the evidence on budgeting, highlighting findings that other theories struggle to explain.

This paper expands our understanding of consumption-savings behavior under self-control problems and the resulting demand for commitment. Since Thaler and Shefrin’s (1981) and Laibson’s (1997) seminal work, the literature has almost always assumed a single, per-period, commodity (“money”). As this paper shows, that assumption is not innocuous with present-biased consumers (in contrast to the case of time-consistent consumers) and this crucially depends on uncertain intratemporal trade-offs. The literature has focused on the problem of curbing undersaving and the usefulness of devices like illiquid assets and savings accounts. This paper shows that consumers can do strictly better by (also) adopting good-specific budgets, which opens the door to other commitment devices, such as personal budgeting services. It also suggests which type of consumers will demand which type of devices, which can be used by third-party providers.

To derive its results, the paper uses different techniques from the standard mechanism-design approach. The idea is to exploit the information in the Lagrange multipliers for the constraints that budgets and savings floors add to self-1’s optimization problem. Relying on sensitivity-analysis techniques (Luenberger David G. (1969)), we can use this information to quantify, after appropriately adjusting for self-1’s bias, the marginal benefit for self-0 of modifying a budget or a floor.

Related Literature. Existing explanations of personal budgeting are based on Thaler (1985). Using the notions of “transaction utility” and gain-loss utility, he argues that agents treat the consequences of each transaction in isolation. Given this, they can solve their consumption-savings problems by means of transaction-specific budgets, a result which echoes Strotz Robert H. (1957). In reality, people set budgets for sufficiently

---

Brocas Isabelle and Carrillo Juan D. (2008) discuss a model with two goods, one of which has ex-ante uncertain utility, and self-1 is fully myopic. In this case, the optimal commitment strategy consists of a non-linear plan that punishes spending on one good by cutting spending on the other, which is not a budgeting plan. Even if one focuses on these plans, self-0 never sets budgets with a fully myopic self-1 (cf Proposition 3).

This kind of services are currently offered by firms like Mint, Quicken, and StickK.

In reality, it may be hard to observe each consumer’s degree of present bias and offer devices accordingly. Some of the issues that arise in this case are analyzed by Galperti Simone (2015).
long periods so that each covers many transactions. Also, in Thaler’s deterministic model, the agents can achieve the same utility with and without budgets; but with uncertainty, they would never set binding budgets. Therefore, they do not exhibit a strict demand for budgets as commitment devices. Finally, transaction and gain-loss utility differ conceptually from self-control problems, which the literature views as the main cause of budgeting. Gain-loss utility can explain other phenomena of mental accounting, such as choice bracketing (Koch Alexander K. and Nafziger Julia (2016)), which however differ from budgeting.

Other papers in the mechanism-design literature studied the trade-offs between commitment and flexibility, usually imposing no restriction on the feasible mechanisms. Amador Manuel et al. (2006) and Halac Marina and Yared Pierre (2014) are the closest to the present paper.9 It borrows their baseline model, but adds multiple consumption goods and uncertainty about intratemporal trade-offs. In so doing, it shows how this uncertainty affects the commitment-flexibility trade-off and its solutions. Another difference is that Halac Marina and Yared Pierre (2014) focus on the role of information persistency. In their setting, an optimal commitment plan can distort future choices, even though they cause no conflict between the agent’s selves given today’s choice. Persistency links self-1’s current information and expected utility from future choices, which can be used to relax today’s incentive constraints, as in other dynamic mechanism-design problems.10 Correlation among self-1’s pieces of information is not the driver of the present paper’s results.

An older literature examined how rationing affects consumer behavior (Howard David H. (1977), Ellis Christopher J. and Naughton Barry J. (1990), Madden Paul (1991)). By setting a savings floor or good-specific budgets, an agent essentially rations his future selves as the government may ration consumers. In contrast to that literature, here rationing assumes the role of a commitment device. That literature showed that predicting the budgets’ effects is far from trivial. Its insights will be useful to identify conditions under which budgets can help the agent.

2 The Model

Consider an agent, Ann, who lives for two periods. In the first, she chooses a consumption bundle \( c = (c_1, c_2) \in \mathbb{R}_+^2 \) and a level of savings \( s \in \mathbb{R}_+ \). In the second period, consumption involves a single good and hence equals \( s \). Ann receives her income, normalized to 1, in the first period.

Ann has self-control problems, caused by a conflict between a long-run self-0 and a short-run self-1. Their preferences depend on some taste shocks, represented by the state \((\theta, r_1, r_2)\), where \( \theta > 0 \) and \( r = (r_1, r_2) \in \mathbb{R}^2 \). In each period both selves have the same (concave) consumption utility: \( u(c; r) \) in period 1 and \( v(s) \) in period 2. In period 1,

9See also Athey Susan et al. (2005), Ambrus Attila and Egorov Georgy (2013), and Amador Manuel and Bagwell, Kyle (2013).
10See, for example, Courty Pascal and Li Hao (2000), Battaglini Marco (2005), Pavan Alessandro et al. (2014).
however, self-0 and self-1 evaluate streams \((c, s)\) using respectively the utility functions
\[
\theta u(c; r) + v(s) \quad \text{and} \quad \theta u(c; r) + \beta v(s).
\]
For clarity and tractability, for now assume that
\[
u(c; r) = \frac{\partial^2 u^i(c_i; r_i)}{\partial c_i \partial r_i} = u_{cr}^i(c_i; r_i) > 0 \quad \text{for} \quad i = 1, 2.
\]
Self-1’s present bias is captured by \(\beta \in (0, 1)\). Self-0 knows \(\beta\) (sophistication); we will discuss naïveté later.

A key novelty of this model is that the state affects both inter- and intratemporal trade-offs. While \(\theta\) affects only the substitution rate between present and future utility, \(r\) also affects the substitution rates between goods within period 1. Hereafter, let \(\omega = (\theta, r)\), \(G\) be its distribution, and \(\Omega\) the state space. \(G\) is allowed to have rich forms of dependence as well as full independence across \(\theta, r_1,\) and \(r_2\).

Self-0 delegates the consumption-savings choice to self-1 by designing a commitment plan dictating which choices self-1 is allowed to implement. In the case of budgeting, such a plan involves spending limits on specific consumption categories, denoted by \(b_i\) (for budget), or an overall limit on consumption expenditures implemented through a minimum-savings rule \(f\) (for floor). Formally, let
\[
F = \{(c, s) \in \mathbb{R}_+^3 : c_1 + c_2 + s \leq 1\}.
\]
Think of \(c_i\) and \(s\) as the share of income allocated to good \(i\) and savings. A budgeting plan, \(B\), can then be expressed as follows:
\[
B = \{(c, s) \in F : s \geq f, c_1 \leq b_1, c_2 \leq b_2\},
\]
where \(f \in [0, 1]\) and \(b_i \in [0, 1]\) for \(i = 1, 2\). Let \(\mathcal{B}\) be the set of all budgeting plans. From the ex-ante viewpoint, we will call \(f\) and \(b_i\) binding if they bind with strictly positive probability under \(G\). Note that \(\mathcal{B}\) defines a specific subclass of commitment plans which—though intuitive and tractable—rules out many other possible ways of restricting self-1’s choices. Section 4 discusses some intricacies of allowing for more general plans.

In reality, agents commit to their plans prior to observing all the necessary information for making a decision. This creates a trade-off between commitment and flexibility. In the model, first self-0 commits to a plan \(B\), then only self-1 observes \(\omega\) and chooses some \((c, s)\) from \(B\). Self-0 designs \(B\) to maximize her expected payoff from self-1’s choices. Note that if self-0 knew \(\omega\), the problem would be uninteresting: Setting \(f\) at the level of savings that self-0 finds optimal given \(\omega\) always induces self-1 to choose \(c\) and \(s\) that maximize self-0’s utility.

The goal of the paper is to understand whether and how self-0 sets minimum-savings rules and good-specific budgets. The problem can be stated as
\[
\max_{B \in \mathcal{B}} \mathcal{U}(B) = \int_{\Omega} [\theta u(c(\omega); r) + v(s(\omega))] dG(\omega) \quad (1)
\]
s.t. \((c(\omega), s(\omega)) \in \arg \max_{(c,s) \in B} \theta u(c; r) + \beta v(s), \quad \omega \in \Omega. \quad (2)
\]
A solution will be called an optimal plan.
Technical Assumptions

Information distributions: Let $\Omega = [\theta, \bar{\theta}] \times [\underline{r}_1, \bar{r}_1] \times [\underline{r}_2, \bar{r}_2]$, where $0 < \theta < \bar{\theta} < +\infty$ and $0 < \underline{r}_i < \bar{r}_i < +\infty$ for $i = 1, 2$. We will only assume that the joint probability distribution $G$ of $(\theta, r_1, r_2)$ has full support (that is, $G(\Omega) > 0$ for every open $\Omega \subset \Omega$). The conditions on $\theta$ and $\bar{\theta}$ rule out the implausible situation where Ann does not care at all about the present or the future.\footnote{A similar assumption appears in Amador Manuel et al. (2006), who point out that with unbounded support it may be optimal to grant self-1 full flexibility.} The conditions on $\underline{r}_i$ and $\bar{r}_i$ have bite only when combined with the properties of $u$ listed next.

Differentiability, monotonicity, concavity: $v$ is twice continuously differentiable with $v' > 0$ and $v'' < 0$. For $i = 1, 2$ and $r_i \in [\underline{r}_i, \bar{r}_i]$, $w^i(\cdot; r_i) : \mathbb{R}_+ \to \mathbb{R}$ is twice differentiable with $w'^i(\cdot; r_i) > 0$ and $w''^i(\cdot; r_i) < 0$; also, $u^i_c$ and $u^i_{cc}$ are continuous on $(0, 1] \times [\underline{r}_i, \bar{r}_i]$. This implies that $u^i_c$ is bounded below and away from zero; this non-satiation property seems plausible to the extent that $i$ refers to “food,” “housing,” or “entertainment” and a period corresponds to a week or a month.

Boundary conditions: $\lim_{s \to 0} v'(s) = +\infty$ and $\lim_{c \to 0} u^i(c; r_i) = +\infty$ for $r_i \in [\underline{r}_i, \bar{r}_i]$ and $i = 1, 2$. This will allow us to focus on interior solutions.

Discussion of the Model

Nothing significant changes if Ann receives income in both periods and can borrow in period 1, or if the consumption bundle $c$ involve more than two goods. In fact, the proofs consider the general case of $n \geq 2$ goods. It is straightforward to allow for multiple goods also in the second period.

The two selves’ preferences are consistent with the quasi-hyperbolic discounting model of Laibson David (1997) and with viewing the agent as a household aggregating its members’ preferences, which are time consistent but heterogeneous (Jackson Matthew O. and Yariv Leeat (2015)). A public finance interpretation of the model is also possible along the lines of Halac Marina and Yared Pierre (2014). In each period, a government chooses spending on a list of public goods and services, $c$, and saving or borrowing, $s$, subject to the constraint given by the tax revenues. The government may exhibit present bias as a consequence of aggregating the preferences of heterogeneous citizens (Jackson Matthew O. and Yariv Leeat (2015)) or uncertainty in the political turnover (Aguiar Mark and Amador Manuel (2011)).

The assumed information structure has some redundancy, as both an increase in $\theta$ and an increase in all components of $r$ render period-1 consumption more valuable. Nonetheless, it is convenient for differentiating uncertainty about intra- and intertemporal trade-offs and for showing that the former is crucial for budgets to arise (Section 3.2). In a nutshell, this is because it allows for situations where overspending is driven by all goods and situations where it is mostly driven by only some good.

To focus on the issues of interest for this paper, it is assumed that Ann sticks to her plans. This is not a minor assumption, of course, but the literature has proposed several mechanisms which can justify it. These include a desire for internal consistency (Festinger
Leon (1962)), the plans’ working as reference points (Heath Chip et al. (1999), Hsiaw Alice (2013)), self-reputation mechanisms (Benabou Roland and Tirole Jean (2004)), internal control processes that prevent impulsive processes from breaking ex-ante rules (Benhabib Jess and Bisin Alberto (2005)), and self enforcement sustained by threats of switching to less desirable equilibria (Bernheim B. Douglas et al. (2015)). Perhaps in reality people are able to carry out their plans provided that they are not too stringent or costly ex post. Even in this case, it is worth understanding which forces lead people to find budgets and floors useful despite their ex-post inefficiency. For instance, some present-biased agents may not use budgets not because they cannot stick to them, but simply because they do not find them useful. This can also be valuable for third parties which design commitment devices to help people stick to their plans (such as firms like Mint, Quicken, and StickK).

3 Optimal Budgeting Plans

3.1 Preliminaries

First of all, treating self-0’s payoff as a function of \( f, b_1 \), and \( b_2 \), one can easily establish existence of an optimal plan using the Maximum Theorem.\(^{12}\)

It is worth defining two benchmark allocations. For each \( \omega \), let \((c^d(\omega), s^d(\omega))\) be self-1’s choice if granted full discretion, namely, the solution to \( \max_{(c,s) \in F} \{ \theta u(c;r) + \beta v(s) \} \).

Also, let \((c^p(\omega), s^p(\omega))\) represent what self-0 would like self-1 to choose in \( \omega \), which is the solution to \( \max_{(c,s) \in F} \{ \theta u(c;r) + v(s) \} \). Call \((c^d, s^d)\) the full-discretion allocation and \((c^p, s^p)\) the first-best (or planned) allocation. They satisfy the following useful properties.

Remark 1.
1. \((c^p, s^p)\) and \((c^d, s^d)\) are continuous in \( \omega \);
2. Each component of \((c^p, s^p)\) and \((c^d, s^d)\) takes values in a closed interval and is bounded away from zero;
3. For \( i = 1, 2 \), \( c^d_i \) and \( c^p_i \) are strictly increasing in \( r_i \) and \( \theta \) and decreasing in \( r_j \) for \( j \neq i \);
4. \( s^p_i \) and \( s^d_i \) are strictly decreasing in \( \theta, r_1 \), and \( r_2 \);
5. For \( \omega \in \Omega \), \( s^d(\omega) < s^p(\omega) \) and \( s^d(\omega) \) is continuous and strictly increasing in \( \beta \);
6. For \( \omega \in \Omega \) and \( i = 1, 2 \), \( c^d_i(\omega) \) is continuous and strictly decreasing in \( \beta \).

Another property worth noting is that all consumption goods are normal for both selves.\(^{13}\)

For illustration, consider a fully symmetric model with respect to good 1 and 2. Since self-1 saves whatever he does not consume \( (v' > 0) \), we can focus on his choices of \( c \) represented in Figure 1. Note that \( c \)’s on negative-45° lines closer to the origin correspond to a higher \( s \). To understand the shape of \( c^p \), suppose for the moment that \( \theta \) takes only one value. Start from \((\theta, \bar{r}_1, \bar{r}_2)\), which leads to the highest \( s \). If we raise \( r_1 \) up to \( \bar{r}_1 \), \( c^p_1 \) increases while \( c^p_2 \) and \( s^p \) decrease, which means that we move along the south part of the dashed line. If we now start from \((\theta, \bar{r}_1, \bar{r}_2)\) and raise \( r_2 \) up to \( \bar{r}_2 \), \( c^p_2 \) increases while \( c^p_1 \) and

\(^{12}\)See the Online Appendix.

\(^{13}\)This property follows, for instance, from Proposition 1 in Quah John K-H (2007).
$s^p$ decrease; that is, we move along the east part of the dashed line. Proceeding this way, we can map the entire dashed line; continuity of $c^p$ implies that its range extends inside the boundary in Figure 1. Self-1’s systematic undersaving shifts the $c^d$ region away from the origin; the stronger his bias, the bigger the shift. Figure 1 also highlights the effect of uncertain intratemporal trade-offs. If $r$ were certain (but not $\theta$), both $c^p$ and $c^d$ would collapse to an upward sloping line so that the state calling for minimal savings always coincides with that calling for maximal consumption of both goods.

3.2 A Benchmark: Known Intratemporal Trade-offs

This section shows that if we remove the uncertainty about intratemporal trade-offs—while keeping that about the intertemporal trade-off and multiple goods—then most of the time optimal plans involve a savings floor but no good-specific budgets. This benchmark will help us disentangle the role of uncertain intratemporal trade-offs from the multidimensionality of consumption.

For the sake of the argument, in this section imagine that self-0 observes $r$ (but not $\theta$) before designing her plan—self-1 continues to observe $\theta$ and $r$. We can then examine the problem defined by (1) and (2) treating $r$ as fixed. Let $G_r$ denote the distribution of $\theta$ given $r$. To state the result, we need some minor conditions about $G_r$. Assume that $G_r$ has a strictly positive, continuous, density function $g_r$ on $[\underline{\theta}, \overline{\theta}]$. Define

$$H(\theta) = 1 - G_r(\theta) - (1 - \beta)\theta g_r(\theta), \quad \theta \in [\underline{\theta}, \overline{\theta}],$$

and

$$\theta^* = \min \left\{ \theta \in [\underline{\theta}, \overline{\theta}] : \int_{\theta}^{\overline{\theta}} H(\hat{\theta}) d\hat{\theta} \leq 0 \text{ for all } \theta' \geq \theta \right\}.$$

Proposition 1. Suppose $H$ is non-increrasing over $[\underline{\theta}, \theta^*]$. Then, a plan $B$ that satisfies $f = s^d(\theta^*)$ and $b_1 = b_2 = 1$ is optimal.

As Amador Manuel et al. (2006) noted, for many distributions—especially those commonly used in applications—$H$ satisfies the above condition for all $\beta \in [0, 1]$. More generally, if $g_r$ is uniformly bounded away from 0 and changes at a bounded rate, the
condition on $H$ holds when $\beta$ is sufficiently high. Importantly, as we will see, high $\beta$s characterize the settings with uncertain intratemporal trade-offs where plans using only $f$ are not optimal.

Proposition 1 follows from Amador et al.’s (2006) main result, once we establish the following key point: If self-0 knows $r$, she can focus on commitment plans that regulate only savings and total consumption expenses, but not how these are divided between goods. The reason is as follows. Unlike a binding $f$, which distorts only the income division between spending and saving, a binding $b_i$ also distorts consumption. Thus, by forcing self-1 to consume inefficient bundles, budgets lower the utility he can get from what he does not save. To lower this utility, however, another method is simply to not let self-1 spend all of $1 - s$. The literature called this “money burning.” Spending a share of $1 - s$ efficiently can achieve any utility obtained by spending $1 - s$ inefficiently: For all $c_2 \in \mathbb{R}^2_+$ there exists $y \leq c_1 + c_2$ that yields $u(c; r) = u^*(y; r)$, where $u^*(y; r)$ is the indirect utility of spending $y$. Different realizations of the intratemporal trade-offs may affect how self-0 wants to “punish” self-1 for undersaving, holding $s$ fixed. But without that uncertainty, the optimal punishment is unique and can always be achieved with money burning, provided that its amount can flexibly depend on the chosen $s$. This requires more general forms of commitment than budgeting plans. Formally, let

$$F^{tc} = \{(y, s) \in \mathbb{R}^2_+ : y + s \leq 1\}.$$ Given $D^{tc} \subset F^{tc}$, self-1 maximizes $\theta u(c; r) + \beta v(s)$ subject to $c_1 + c_2 \leq y$ and $(y, s) \in D^{tc}$.

**Lemma 1.** Suppose uncertainty affects only the intertemporal utility trade-off. There exists an optimal $D \subset F$ with $U(D) = U^*$ if and only if there exists an optimal $D^{tc} \subset F^{tc}$ with $U(D^{tc}) = U^*$.16

Thus, when only the intertemporal trade-off is uncertain, whether consumption involves one or multiple goods is irrelevant, as long as we allow for general commitment plans.

Proposition 1 goes one step further by showing that the number of consumption goods is irrelevant even when self-1 can use only minimum-savings rules. Given Lemma 1, since the constraint $c_1 + c_2 \leq y$ will always bind for self-1, the problem becomes

$$\max_{D^{tc} \subset F^{tc}} \int_{\theta} \left[ \theta u^*(y(\theta); r) + v(s(\theta)) \right] g_r(\theta) d\theta$$

s.t. $(y(\theta), s(\theta)) \in \arg \max_{(y, s) \in D^{tc}} \{\theta u^*(y; r) + \beta v(s)\}$, $\theta \in [\theta, \overline{\theta}]$.

This is isomorphic to the problem studied by Amador Manuel et al. (2006). Proposition 1 then follows from their Proposition 3.

---

14One way to see this is that the positive Lagrange multiplier for the binding $c_i \leq b_i$ introduces a wedge between the goods’ marginal utilities.

16This lemma follows from an argument similar to that establishing the revelation principle. See the Online Appendix for details.
3.3 Main Results

We now returns to the model where both inter- and intratemporal trade-offs are uncertain for self-0. The next result is in sharp contrast with the benchmark established before.

**Proposition 2.** There exists \( \beta^* \in (0, 1) \) such that, if \( \beta^* < \beta < 1 \), then every optimal \( B \in \mathcal{B} \) must include binding good-specific budgets.\(^{17}\)

The Appendix shows how to derive \( \beta^* \), which can be significantly smaller than 1. Proposition 2 is silent about whether good-specific budgets are always combined with a floor. Section 3.4 shows that both cases are possible.

Do optimal plans always require good-specific budgets? The answer is no.

**Proposition 3.** There exists \( \beta_* \in (0, 1) \) such that, if \( \beta < \beta_* \), then every optimal \( B \in \mathcal{B} \) involves only a binding savings floor.

The Appendix shows how to calculate \( \beta_* \), which can be significantly larger than 0 and depends on \( G \) only through its support. Using this, we can show that weaker biases suffice to render budgets suboptimal when the uncertainty on intratemporal trade-offs shrinks in the following sense.

**Corollary 1.** Consider two agents who have the same utility functions \( u \) and \( v \) and their uncertainty has supports \( [\underline{\theta}, \bar{\theta}] \times [\underline{\tau}_1, \bar{\tau}_1] \times [\underline{\tau}_2, \bar{\tau}_2] \) and \( [\underline{\theta}, \bar{\theta}] \times [\underline{\tau}'_1, \bar{\tau}'_1] \times [\underline{\tau}'_2, \bar{\tau}'_2] \). Let \( \beta_* \) and \( \beta'_* \) be the corresponding thresholds in Proposition 3. If \( (\underline{r}_1, \underline{r}_2) \geq (\underline{r}'_1, \underline{r}'_2) \) and \( (\bar{r}_1, \bar{r}_2) \leq (\bar{r}'_1, \bar{r}'_2) \), then \( \beta'_* > \beta_* \).

This corollary echoes the benchmark result of Section 3.2: That case corresponds to the limit as \( r_i \to 0 \) for \( i = 1, 2 \). We saw that, under minor conditions, in the limit essentially \( \beta_* = 1 \).

One subtlety of the model is that \( f \), \( b_1 \), and \( b_2 \) can bind simultaneously, thereby affecting self-1’s choices in possibly complex ways. To handle this, the proof proceeds in several steps, which are sketched here to also uncover the intuitions for the results.

The first step is to consider how self-0 would use \( f \) in isolation. In this case, the best \( f \) lies strictly between the highest and lowest first-best savings, \( \mathfrak{r}^p \) and \( s^p \), and rises as \( \beta \) falls. Though similar, this step is not a corollary of Amador et al.’s (2006) results and uses different techniques. Intuitively, self-0 never finds any \( s < s^p \) justifiable, and \( f \) never distorts the chosen \( c \) because the two selves have the same consumption utility \( u \). Consequently, self-0 always sets \( f \geq s^p \). Setting \( f = s^p \) cannot be optimal, as raising \( f \) a bit causes a second-order loss when \( s^p(\omega) = s^p \), but a first-order gain when \( s^p(\omega) > s^p \) and \( f \) binds. A similar logic explains why \( f < \mathfrak{r}^p \). Thus, \( f \) has to balance the benefit of curbing undersaving and the cost of causing oversaving. A lower \( \beta \) raises the optimal \( f \) because the benefit of raising \( f \) grows if self-1 tends to undersave more, but the cost stays the same: When self-0 wants \( s < f \), self-1 does too and \( f \) binds for any \( \beta \). To obtain these properties, the proof shows that the derivative of self-0’s payoff in \( f \) exists,

\(^{17}\)All proofs are in the Appendix.
has a simple form, and is decreasing in $\beta$. This uses the fact that we can focus on the states where $f$ will bind for self-1 and so $s = f$, which allows us to immediately infer the effect of varying $f$ on self-0’s savings utility, $v$. Since both selves share $u$, the effect on self-0’s consumption utility can be inferred from self-1’s indirect utility from spending $1 - f$ via Lagrangian sensitivity analysis, which links this effect to the marginal utility of any good at the chosen $c$. These effects are shown to matter for a set of states with strictly positive probability using the continuity of self-1’s choices in $f$ and $\omega$ and the full support of $G$.

The second step is to consider how self-0 would use $b_i$ in isolation. It turns out that capping even only one good dominates granting self-1 full discretion. To see why, start from the level of $b_i$ where it starts to bind (i.e., $b_i = \tau_i^d = \max_\omega c_i^d(\omega)$). Lowering $b_i$ creates a benefit and a cost for self-0, when $b_i$ binds. The cost is that it distorts consumption. But this is initially a second-order cost, because the full-discretion $c^d$ is efficient, in the sense of equalizing marginal utilities between goods. The benefit is that $b_i$ curbs undersaving, which is of first-order importance for self-0. Overall $b_i$ should then benefit self-0, but there is a subtlety: Self-1 should not reallocate income to the unrestricted $c_j$ much faster than to $s$, which is not obvious and need not be true. This key property holds for the additively separable $u$, but also more generally (cf Section 4). Once this is established, the proof uses the fact that both selves share $u$ to show that self-0’s payoff can be written as her savings utility scaled by $(1 - \beta)$ plus self-1’s total payoff subject to $b_i$. Lagrangian sensitivity analysis on the latter pins down the second-order negative effects of $b_i$. The former part directly quantifies the first-order positive effects of $b_i$. These effects again matter for a set of states with strictly positive probability for the same reasons as before.

These points highlight the general mechanism whereby multidimensional consumption can help to curb the consequences of present bias. A budget $b_i$ incentivizes self-1 to save more because it forces him to choose inefficient bundles—not just to spend less on $c_i$, which he could fully shift to $c_j$—and this inefficiency limits the present utility self-1 can gain by undersaving.

![Figure 2: Optimal Budgeting Plans – Intuition](image-url)

(a) Strong Bias  
(b) Weak Bias

Figure 2: Optimal Budgeting Plans – Intuition
The above two steps are combined to obtain Proposition 2. Intuitively, when present bias is weak an optimal plan must use budgets because they help improve savings when doing so via $f$ would require it to be too tight. Consider Figure 2, which focuses on consumption choices and reports the full-discretion and first-best allocations from Figure 1. Graphically, $b_1$ defines a vertical line allowing only $c_1$’s to its left, $b_2$ defines a horizontal line allowing only $c_2$’s below it, and $f$ defines a line with slope $-1$ allowing only $c$’s below it. Thus, in Figure 2(b) for instance, self-1 must choose $c$ within the diamond-shaped region to the south-west of the solid lines $f$, $b_1$, and $b_2$. Uncertain intratemporal trade-offs imply that the states where both selves want to spend the most on $c_1$ or $c_2$ (which map to the light-shaded areas) are not the states where they want to save the least (which map to the dark-shaded areas). Indeed, by Remark 1 for $i = 1, 2$ and $k = p, d$

$$v^k_i = c^k_i(\bar{\theta}, \bar{r}_i, \bar{r}_{-i}) > c^k_i(\bar{\theta}, \bar{r}_i, \bar{r}_{-i}) \quad \text{and} \quad s^k = s^k(\bar{\theta}, \bar{r}_i, \bar{r}_{-i}) < s^k(\bar{\theta}, \bar{r}_i, \bar{r}_{-i}).$$

We saw that if self-0 can use only $f$, she relaxes it as $\beta$ rises; that is, the $f$ line moves farther away from the origin. Consequently, $f$ constrains choices in the dark-shaded area, but at some point stops affecting them in the light-shaded areas—compare panel (a) to (b). To curb undersaving in these states, self-0 prefers not to use $f$, but can add budgets that bind when $f$ does not (as in (b)). As noted, such budgets benefit self-0.

The proof of Proposition 3 first shows that it is never optimal to let self-1 save $s < s^p$. Intuitively, if $B$ allows this, raising $f$ up to $s^p$ uniformly improves self-0’s savings utility; moreover, since all goods are normal, the resulting lower spendable income renders any budget in $B$ less likely to bind and distort $c$, which again benefits self-0. Now note that when $\beta$ is sufficiently small, self-1 always wants to save $s < s^p$. Hence, when $b_i$ forces self-1 to spend less on $c_i$, he shifts all the money to $c_j$, but not $s$. Since budgets distort $c$, if they do not raise $s$, they cannot benefit self-0 and hence be part of optimal plans.

It is now easy to see why shrinking uncertainty about intratemporal trade-offs expands the set of strong biases for which optimal plans use only $f$ (Corollary 1). Budgets are useful to curb undersaving in states with large asymmetry in the goods’ marginal utilities (recall Figure 2). If this asymmetry shrinks, so does the scope for budgets to be useful.

As should be expected, the strongest bias for which optimal plans use good-specific budgets depends on the details of the context. This does not change the main takeaway. As $\beta$ falls, for every $B$ it raises the probability of the states where self-1 is constrained by $B$’s actual lower bound on savings at some $\tilde{s} > s^p$. Since in these states binding budgets only distort $c$, their appeal falls accordingly. How self-0 balances the distortions in those states with the budgets’ benefits in other states ultimately depends on their distribution $G$. Nonetheless, since self-0 can always set $f = \tilde{s}$, for $\beta$’s below some $\hat{\beta} \geq \beta_*$ every optimal plan must use only $f$.

Finally, one may think that these results are driven by the fact that budgets and the savings floor are substitute tools—in the sense that, everything else equal, optimal plans set a slacker $f$ if they can also use $b_1$ and $b_2$. Their interaction is actually more subtle. By curbing self-1’s undersaving, $b_1$ and $b_2$ lower the return of tightening $f$, which can result in a slacker $f$. At the same time, $b_1$ and $b_2$ also lower the return of loosening $f$ because they prevent self-1 from consuming efficiently the extra spendable income, which can result in a tighter $f$. Therefore, when agents can also use budgets, their savings floor
There exist full-support distributions sufficiently close to by considering a three-state case. Let for every optimal .%

In a given week, Ann may go out with Becky (again on consumption. Concretely, imagine that Ann has two friends, Becky and Cindy. Cindy). 

This section shows that with multiple goods there exist both settings where self-0 combines budgets with a savings floor and settings where she uses only the budgets. By contrast, in the case of a single good optimal plans always involve a binding floor.

Proposition 4. There exist full-support distributions such that , and are all binding for every optimal . There also exist full-support distributions such that, for every optimal , and are binding, but never binds.

While the result holds for full-support distributions, its intuition can be best explained by considering a three-state case. Let , and with respective probabilities , . This claim is shown as part of the constructive proof of Proposition 4. The specific levels of and are just a byproduct of logarithmic payoffs.

\[ s^d(\omega^0) < s^d(\omega^1) = s^d(\omega^2), \quad c^d(\omega^1) = c^d(\omega^2) = c^d(\omega^3) = c^d(\omega^0); \]

similar properties hold for . By continuity, there exists sufficiently high that ; hereafter, fix such a . There exists sufficiently close to such that and . Figure 3(a) represents this situation, focusing again on consumption. Concretely, imagine that Ann has two friends, Becky and Cindy. In a given week, Ann may go out with Becky ( ), Cindy ( ), or both together ( ). Bekk likes shopping for clothes with Becky and trying new restaurants with Cindy. When out with both, she enjoys both activities even more. Finally, Ann anticipates that, once in the store or the restaurant, she will tend to spend too much.

One can show that if Ann deems going out with both friends sufficiently likely (i.e., ), then she wants to set a binding as well as budgets for both goods. In fact, the optimal satisfies . The intuition is this. If Ann was sure to go out with one friend at a time, she could set so as to eliminate splurging in and —this corresponds to the dotted line in Figure 3(a). However, this will be too stringent if she ends up going out with both friends. Since this is very likely, Ann prefers this will not bind when she is out with only one friend. But for this case she can curb overspending using and ; also, here she can do so without affecting her choice in .

---

\[ s^d(\omega^0) = s^d(\omega^1) = s^d(\omega^2), \quad c^d(\omega^1) = c^d(\omega^2) = c^d(\omega^3) = c^d(\omega^0); \]

\[ s^d(\omega^1) = s^d(\omega^2) > s^d(\omega^0); \]

---

See Proposition 2 and 10 in Amador Manuel et al. (2006).

The function violates the continuity and differentiability assumptions of Section 2 at 0, but this is irrelevant for the analysis.

This claim is shown as part of the constructive proof of Proposition 4. The specific levels of and are just a byproduct of logarithmic payoffs.
A simple change of this three-state setting suffices to explain why optimal plans can involve only good-specific budgets. Fix $g > g^*$ and all the other parameters, except $\overline{\theta}$. If we increase $\overline{\theta}$, both selves want to consume more in $\omega^0$. This eventually leads to a situation as in Figure 3(b), where $c^p_1(\omega^0) > c^d_1(\omega^0)$ and $c^p_2(\omega^0) > c^d_2(\omega^0)$. In this case, Ann wants to keep $b_1$ and $b_2$, but drop $f$. In fact, her optimal $B$ satisfies $b_1 = b_2$ and $c^p_i(\omega^0) < b_i < c^d_i(\omega^0)$ for every $i = 1, 2$, but $f = 0$. Figure 3(b) helps with the intuition. Now Ann is willing to spend even more in $\omega^0$. Therefore, the budgets she would set to curb splurging in $\omega^1$ and $\omega^2$ start to bind also in $\omega^0$. As a result, she wants to relax them. She realizes, however, that her first-best spending on clothes and food in $\omega^0$ is just above these budgets. Relaxing them a bit will allow her to curb splurging in $\omega^1$ and $\omega^2$ as well as $\omega^0$. Since these budgets already push savings above the first best in $\omega^0$, Ann cannot benefit by adding a binding $f$.

In short, a weakly present-biased agent may use only good-specific budgets for the following reason. To curb undersaving in states with large asymmetry in consumption marginal utilities, she may prefer to use the budgets rather than a savings floor, which would have to be too stringent. Together the budgets then impose a cap on total spending. If this already ensures sufficiently high savings in states where present consumption is very valuable overall, then any binding floor will have to cause additional oversaving and this inefficiency can exceed the floor’s commitment benefits.

4 Discussion

Theory and Evidence. How does this theory relate to the evidence on budgeting and other explanations thereof? One finding is that people may set budgets on “unobjec-
tionable goods like sports tickets and blue jeans” (Heath Chip and Soll Jack B. (1996)) or housing, food, and even charitable giving (Thaler (1985, 1999)). This is difficult to explain with an alternative theory arguing that people set budgets for the goods they find tempting (“vice goods”)—although this can be true in some cases. By contrast, present bias combined with uncertain intratemporal trade-offs can lead people to set budgets on “unobjectionable goods,” as doing so helps them manage their overall tendency to overspend better than with just a savings floor. Thus, it is not the tempting nature of a good that matters.

Another plausible theory is that budgeting is a technique to simplify the complex matter of household finance (Simon Herbert A. (1965); Johnson Michael D. (1984)). This theory is complementary to the one in this paper, but again struggles to explain some evidence. For instance, it is not clear why computational complexity would lead people to systematically set budgets which seem too strict and to cause underconsumption, as found by Heath Chip and Soll Jack B. (1996). By contrast, present-biased people do optimally set budgets that systematically bind and thus exhibit those properties.

The prediction that only weakly biased agents should use good-specific budgets is consistent with some findings in Antonides Gerrit et al. (2011). In their sample, people who exhibit a “short-term time orientation” (which according to their description is consistent with strong present bias) are less likely to use budgets than people who exhibit a “long-term time orientation” (a weak bias). Unfortunately, Antonides Gerrit et al. (2011) do not measure how stringent budgets or floors are in relation to present bias. For that matter, we saw that this relation need not be monotonic. As an alternative explanation, strongly biased agents may not use budgets because they are less sophisticated or able to commit. The anticipated bias (not the true one) is what matters for self-0’s problem, however. Therefore, by Proposition 2 underestimating that bias—not entirely, of course—may actually render it more likely that self-0 finds budgets beneficial. If this same agent were instead sophisticated, he might not adopt any budget by Proposition 3.

We also saw that once a strongly biased agent can use a savings floor, the reason why budgets do not work for him is not that he cannot honor them: Even if he could, they would strictly lower his utility.

**Relaxing Separability.** The message of the paper generalizes to settings where utility is not separable across goods. Continue to assume that $u(c; r)$ is strictly concave in $c$ and twice differentiable with continuous $u_{ci}(c; r) > 0$ and $u_{cij}(c; r)$ in both arguments for all $i$ and $j$. We saw that budgets help curb self-1’s undersaving if (a) they increase savings and (b) there exist states which call for high consumption of some good, but not of all goods. Property (b) holds if some good is a sufficiently strong substitute of all other goods. Property (a) holds if the capped good is a Hicks substitute of savings (Howard David H. (1977)); in general, such a good always exists (Madden Paul (1991), Theorem 2). As noted, however, a budget has to curb undersaving faster than it exacerbates overspending on other goods, for it to benefit self-0. Given space constraints, these properties are stated directly in terms of allocations.

**Condition 1.** Both $(c^p, s^p)$ and $(c^d, s^d)$ are interior for every $\omega$. Both $s^p$ and $s^d$ are strictly decreasing in $\theta$ and $r_i$ for $i = 1, 2$. There exists some good $j$ which satisfies
the following: (1) $c^d_j$ and $c^d_j$ are strictly increasing in $\theta$ and $r_j$ and decreasing in $r_i$ for $i \neq j$; (2) there exists $\varepsilon > 0$ such that, for every $b_j < \max_{\omega} c^d_j(\omega)$, self-1’s optimal $(e^*, s^*)$ subject to plans involving only $b_j$ satisfies $s^*(\omega) - s^d(\omega) \geq \varepsilon [c^d_j(\omega) - c^*_j(\omega)]$ for all $\omega \in \Omega$.

The Online Appendix presents an example which satisfies Condition 1.

To state the result, consider a more general class of budgeting plans, denoted by $B$, which allow to also set good-specific floors and a savings cap:

$$B = \{ (c, s) \in F : f_0 \leq s \leq b_0, f_1 \leq c_1 \leq b_1, f_2 \leq c_2 \leq b_2 \},$$

where $f_i, b_i \in [0, 1]$ satisfy $f_i \leq b_i$ for $i = 0, 1, 2$ and $f_0 + f_1 + f_2 \leq 1$.

**Proposition 5.** Under Condition 1, there exists $\beta^* \in (0, 1)$ such that, if $\beta^* < \beta < 1$, then every optimal $B$ must use distorting good-specific restrictions.

The proof is omitted, because using Condition 1, one can adapt the proof of Proposition 2 to show that plans using only $f_0$ are strictly dominated for sufficiently high $\beta$. Since setting a binding $b_0$ is never optimal, the result follows.

Do optimal good-specific restrictions always take the form of budgets? The answer depends on the substitutability and complementarity between goods and between each good and savings, which can be affected by the restrictions themselves. A sufficient condition for optimal plans to never use $f_1$ and $f_2$ is that all goods are Hicks substitutes and collectively sufficiently normal (see Ellis Christopher J. and Naughton Barry J. (1990) for a formal statement of this property). Given this, by Theorems 3 and 4 of Madden Paul (1991) two goods remain substitutes independently of which goods are restricted, and Ellis and Naughton’s (1990) analysis implies that, given any $f_1$ and $f_2$, relaxing them raises $s$. Hence, since $f_1$ and $f_2$ distort consumption, they strictly harm self-0. Optimal plans use only $b_1$ and $b_2$ for the example in the Online Appendix.

**General Mechanisms.** One may wonder how the best among all conceivable plans (not just those in $B$) looks like and whether it belongs to $B$. These are important questions, but also hard in the presence of multidimensional consumption and uncertainty. The main challenges come from the income constraint and the complexity of the incentive constraints, which as usual cannot be reduced to only the local ones. One can try to apply here the insights from multidimensional screening (Rochet Jean-Charles and Stole Lars A. (2003)), but substantive differences remain. First, screening problems allow for transfers. Here, one can view the utility from savings as a transfer and use Rochet and Choné’s (1998) approach to simplify the incentive constraints and self-0’s objective. But the state-wise income constraint, the second difference from screening, cannot be simplified. General techniques exist for handling such constraints (Luenberger David G. (1969)), but unlike in the case of unidimensional consumption, here they do not go far.

**5 Concluding Remarks**

This paper provides a theoretical analysis of the link between self-control problems and personal budgeting using a parsimonious consumption-savings model with a present-biased agent. Unlike minimum-savings rules, good-specific spending caps help to curtail
overspending because they cause inefficiencies in consumption which lower the return from undersaving, thereby counteracting present bias. Consequently, good-specific budgets are no free lunch and are used only by agents who are weakly biased and uncertain about their intratemporal trade-offs between goods. Those who are strongly biased or do not face such uncertainty prefer to rely exclusively on a minimum-savings rule.

This theory offers insights into the subtle forces underlying a widely observed phenomenon, which has far-reaching consequences for consumer behavior and welfare by affecting demand differently from satiation and income effects and by significantly contributing to households’ wealth accumulation. The theory matches existing empirical findings, such as that often people set budgets for goods normally not viewed as tempting and only those who exhibit weak present bias seem to use budgets. The theory also suggests new directions for enriching the sparse evidence on budgeting by demonstrating its dependence on uncertain intratemporal trade-offs, and for designing commitment devices whose functions are targeted to the right type of present-biased agents.

6 Appendix

6.1 Technical Lemmas

**Lemma 2.** Fix \( i \in \{1, \ldots, n\} \) and consider \( B \in \mathcal{B} \) with \( b_j = 1 \) for all \( j \neq i \). For any \( \omega \), if \( b_i < c_i^d(\omega) \), self-1 chooses \( s > s^d(\omega) \) and \( c_j > c_j^d(\omega) \) for all \( j \neq i \).

**Proof.** Let \( i = 1 \) and \( b_1 \in (0, c_1^d(\omega)) \). Consider self-1’s problem in state \( \omega \) to maximize \( \theta u(c, r) + \beta v(s) \) for \( (c, s) \in F \) subject to \( c_1 \leq b_1 \). The first-order conditions of its Lagrangian are \( \beta v'(s(\omega)) = \mu(\omega), \theta u^1(c_1(\omega); r_1) = \mu(\omega) + \lambda_1(\omega), \) and \( \theta u^i(c_i(\omega); r_i) = \mu(\omega) \) for all \( i \neq 1 \), where \( \mu(\omega) \geq 0 \) and \( \lambda_1(\omega) \geq 0 \) are the Lagrange multipliers for \( \sum_{i=1}^n c_i \leq 1 \) and \( c_1 \leq b_1 \).

Suppose \( s(\omega) \leq s^d(\omega) \). Since \( c_1(\omega) = b_1 < c_1^d(\omega) \) and \( s(\omega) + \sum_j c_j(\omega) = s^d(\omega) + \sum_j c_j^d(\omega) = 1 \) by strong monotonicity of preferences, \( c_j(\omega) > c_j^d(\omega) \) for some \( j \neq 0, 1 \). By strict concavity of \( u^i \) and \( v \), \( \theta u^i(c_j(\omega); r_j) < \theta u^i(c_j^d(\omega); r_j) = \beta v'(s^d(\omega)) \leq \beta v'(s(\omega)) \). This violates the first-order conditions for \( \omega \). So we must have \( s(\omega) > s^d(\omega) \). This in turn implies that \( \theta u^i(c_j(\omega); r_j) = \beta v'(s(\omega)) \). By concavity, \( c_j(\omega) < c_j^d(\omega) \) for \( j \neq 1 \).

\[ \square \]

For \( k = p, d \), let \( s^k = \min_{\omega} s^k(\omega) \) and \( \bar{s}^k(\omega) = \max_{\omega} s^k(\omega) \). Focussing on \( f \in [\bar{s}^d, \bar{s}]^{22} \) denote by \( B_f \) the corresponding policy in \( \mathcal{B} \).

**Lemma 3.** Define \( \Omega(f) = \{ \omega \in \Omega : s^d(\omega) \leq f \} \) and let \( c^f(\omega) \) be the maximizer of \( u(c, r) \) subject to \( \sum_{i=1}^n c_i \leq 1 - f \). Then, \( U(B_f) \) is differentiable in \( f \) over \([s^d, \bar{s}] \) with

\[ \frac{d}{df} U(B_f) = \int_{\Omega(f)} \left[ v'(f) - \theta u_{c_i}(c^f(\omega); r) \right] dG, \quad \text{for any } i = 1, \ldots, n. \]

\[ ^{22} \text{Any other } f \text{ is dominated by one in this range.} \]
Proof. Given $f$ and any $\omega$, define

$$
\tilde{u}(f; \omega) \equiv u(c^f(\omega); r) = \max_{\{c \in R^n; \sum_{i=1}^n c_i \leq 1 - f\}} u(c; r). 
$$

(3)

and $\tilde{U}(f; \omega) = \theta \tilde{u}(f; \omega) + v(f)$. Since $u(\cdot; r)$ is strictly concave in $c$, so is $\tilde{u}(\cdot; r)$ in $f$ by standard arguments. Hence, $\tilde{U}(\cdot; \omega)$ is also strictly concave in $f$. Now consider $\tilde{U}''(f; \omega)$. Whenever it is defined, $\tilde{U}''(f; \omega) = \theta \tilde{u}''(f; \omega) + v(f)$. By first-order conditions of the Lagrangian defining $\tilde{u}(f; r)$, we have $u_{c_i}(c^f(\omega); r) = \lambda(\omega; f)$ for $i = 1, \ldots, n$, where $\lambda(\omega; f)$ is the Lagrange multiplier for $\sum_{i=1}^n c_i \leq 1 - f$. Since $c^f(\omega)$ is continuous in $f$ for every $\omega$, so is $\lambda(\omega; f)$. By Theorem 1, p. 222, of Luenberger David G. (1969), $\lambda(\omega; f')(f'' - f') \leq \tilde{u}(f'; r) - \tilde{u}(f''; r) \leq \lambda(\omega; f') (f'' - f')$ for every $f', f'' \in (0, 1)$. Continuity of $\lambda(\omega; \cdot)$ implies that $\tilde{u}'(f; r)$ exists for every $f \in (0, 1)$ and $\tilde{u}'(f; r) = -\lambda(\omega; f) = -u_{c_i}(c^f(\omega); r)$. Therefore,

$$
\tilde{U}''(f; \omega) = v(f) - \theta u_{c_i}(c^f(\omega); r), \quad \omega \in \Omega.
$$

(4)

For any $f$, denote by $(c^f, s^f)$ self-1’s behavior as a function of $\omega$ under $B_f$. By the Maximum Theorem, $(c^f(\omega), s^f(\omega))$ is continuous in both $f$ and $\omega$. Since fixing any $s$ both selves would choose the same $c$ in every $\omega$, by definition

$$
\Psi(f) \equiv U(B_f) = \int_{\Omega} \tilde{U}(s^f(\omega); \omega) dG.
$$

Consider any $f > \hat{f}$ and recall that $\overline{\Omega}(f) = \{\omega : s^d(\omega) \leq f\}$. Then,

$$
\Psi(f) - \Psi(\hat{f}) = \int_{\overline{\Omega}(f)} \left[ \tilde{U}(f; \omega) - \tilde{U}(s^\hat{f}(\omega); \omega) \right] dG
$$

$$
= \int_{\overline{\Omega}(f) \cap (\overline{\Omega}(f))^c} \left[ \tilde{U}(f; \omega) - \tilde{U}(s^f(\omega); \omega) \right] dG + \int_{\overline{\Omega}(f)} \left[ \tilde{U}(f; \omega) - \tilde{U}(\hat{f}; \omega) \right] dG;
$$

the first equality holds because $s^f(\omega) = s^\hat{f}(\omega)$ for $\omega \not\in \overline{\Omega}(f)$ and $s^f(\omega) = f$ for $\omega \in \overline{\Omega}(f)$. Divide both sides by $f - \hat{f}$ and consider the limit as $f \downarrow \hat{f}$. First, for all $\omega$, we have

$$
\lim_{f \downarrow \hat{f}} \frac{\tilde{U}(f; \omega) - \tilde{U}(\hat{f}; \omega)}{f - \hat{f}} = \tilde{U}''(\hat{f}; \omega).
$$

Since $\tilde{U}(\cdot; \omega)$ is concave,

$$
\left| \frac{\tilde{U}(f; \omega) - \tilde{U}(\hat{f}; \omega)}{f - \hat{f}} \right| \leq \max \left\{ \left| \tilde{U}'(f; \omega) \right|, \left| \tilde{U}'(\hat{f}; \omega) \right| \right\}.
$$

Since $\tilde{U}''(f; \omega)$ is continuous in $\omega$ and $f$ as illustrated by (4), $\left| \tilde{U}''(f; \omega) \right|$ is bounded by some $M < +\infty$ for $(f, \omega) \in [s^d, \overline{s}^p] \times \Omega$. Therefore, by Lebesgue’s Bounded Convergence Theorem,

$$
\lim_{f \downarrow \hat{f}} \int_{\overline{\Omega}(f)} \frac{\tilde{U}(f; \omega) - \tilde{U}(\hat{f}; \omega)}{f - \hat{f}} dG = \int_{\overline{\Omega}(f)} \tilde{U}'(\hat{f}; \omega) dG.
$$

Consider now the second part of the limit. Again, by concavity of $\hat{U}(\cdot; \omega)$ and since $s^f(\omega) \in [s^d, \overline{s}^p]$ for $f \in [s^d, \overline{s}^p]$, we have

$$
\left| \frac{\tilde{U}(f; \omega) - \tilde{U}(s^\hat{f}(\omega); \omega)}{f - s^\hat{f}(\omega)} \right| \leq M.
$$

19
Therefore,\[
\left| \int_{\Omega(f) \cap (\Omega(f))^c} \frac{\tilde{U}(f; \omega) - \tilde{U}(s^f(\omega); \omega)}{f - \tilde{f}} \, dG \right| \leq \int_{\Omega(f) \cap (\Omega(f))^c} \frac{\tilde{U}(f; \omega) - \tilde{U}(s^f(\omega); \omega)}{f - \tilde{f}} \, dG
\]
\[
\leq \int_{\Omega(f) \cap (\Omega(f))^c} \frac{\tilde{U}(f; \omega) - \tilde{U}(s^f(\omega); \omega)}{f - s^f(\omega)} \, dG
\]
\[
\leq M \int_{\Omega(f) \cap (\Omega(f))^c} dG.
\]
Observe that $\Omega(f) \cap (\Omega(f))^c = \{\omega : \tilde{f} < s^f(\omega) \leq f\}$, which converges to an empty set as $f \downarrow \tilde{f}$. Since then the second part of the limit converges to zero as $f \downarrow \tilde{f}$, for every $\tilde{f} \in [\vec{s}, \vec{p}]$

$$\Psi'(\tilde{f}+) = \int_{\Omega(f)} \tilde{U}'(\tilde{f}; \omega) dG.$$ 

A similar argument implies that $\Psi'(\tilde{f}-) = \int_{\Omega(f)} \tilde{U}'(\tilde{f}; \omega) dG$ for every $\tilde{f} \in (\vec{s}, \vec{p}]$. Hence, $\Psi(f)$ is differentiable over $[\vec{s}, \vec{p}]$.

6.2 Proof of Proposition 2

The proof uses the following three lemmas.

**Lemma 4.** When self-0 can set only $f$, every optimal $f$ satisfies $\vec{s} < f < \vec{p}$.

**Proof.** We will show that $\Psi'(f) > 0$ for all $f \in (\vec{s}, \vec{p}]$ and $\Psi'(f-) < 0$ for $f = \vec{p}$. Recall that $(c^f, s^f)$ is continuous in $f$ for every $\omega$ and therefore so is $\Psi(f)$. These observations imply that every optimal $f^*$ is in $(\vec{s}, \vec{p})$.

For any $f \in (\vec{s}, \vec{p}]$, define $\Omega^+(f) = \{\omega : s^f(\omega) > f\}$ and $\Omega^-(f) = \{\omega : s^f(\omega) \leq f\}$. For $\omega \in \Omega^+(f)$, consider the fictitious problem maximizing $\theta u(c; r) + v(s)$ for $(c, s) \in \mathbb{R}^{n+1}$ subject to $s + \sum_i c_i \leq 1$ and $s \leq f$. Letting $\mu(\omega)$ and $\phi^+(\omega)$ be the corresponding Lagrange multipliers, the first-order conditions are $v'(s) = \mu(\omega) + \phi^+(\omega)$ and $\theta u_{c_i}(c; r) = \mu(\omega)$ for all $i$. Clearly, $s = f$ and $\phi^+(\omega) > 0$ for $\omega \in \Omega^+(f)$. Also, conditional on $s = f$, both selves would choose the same $c$ in state $\omega$, which is therefore $c^f(\omega)$. Using (4), it follows that, for every $i$,

$$\phi^+(\omega) = v'(f) - \theta u_{c_i}(c^f(\omega); \omega) = \tilde{U}'(f; \omega), \quad \omega \in \Omega^+(f). \tag{5}$$

For $\omega \in \Omega^-(f)$, consider the fictitious problem of maximizing $\theta u(c; r) + v(s)$ for $(c, s) \in \mathbb{R}^{n+1}$ subject to $s + \sum_i c_i \leq 1$ and $s \geq f$. Letting $\mu(\omega)$ and $\phi^-(\omega)$ be the corresponding Lagrange multipliers, the first-order conditions are $v'(s) = \mu(\omega) - \phi^-(\omega)$ and $\theta u_{c_i}(c; r) = \mu(\omega)$ for all $i$. Clearly, $s = f$ and $\phi^-(\omega) \geq 0$ for $\omega \in \Omega^-(f)$. Also, conditional on $s = f$, both selves would choose the same $c$ in state $\omega$, which is therefore $c^f(\omega)$. Using (4), it follows that, for every $i$,

$$\phi^-(\omega) = \theta u_{c_i}(c^f(\omega); r) - v'(f) = -\tilde{U}'(f; \omega), \quad \omega \in \Omega^-(f).$$

---

23Here—and in the other proofs—the complementary slackness conditions are omitted for simplicity.
Consider any \( f \in [s^d, \pi^p] \). Recall that \( \Omega(f) = \{ \omega : s^d(\omega) \leq f \} \). Using Lemma 3, we have

\[
\Psi'(f) = \int_{\Omega(f) \cap \Omega^+(f)} \tilde{U}'(f; \omega) dG + \int_{\Omega(f) \cap \Omega^-(f)} \tilde{U}'(f; \omega) dG = \int_{\Omega(f) \cap \Omega^+(f)} \phi^+(\omega) dG,
\]

where the last equality follows because either \( \Omega^-(f) = \emptyset \) or \( \phi^-(\omega) = 0 \) for \( \omega \in \Omega^-(f) \). The function \( \phi^+(\omega) \) is strictly positive over \( \Omega(f) \cap \Omega^+(f) \). We need to show that \( G(\Omega(f) \cap \Omega^+(f)) > 0 \), which implies \( \Psi'(f) > 0 \). This is immediate if \( f \in (s^d, \pi^p) \), because \( \Omega^+(f) = \Omega \). Consider \( f = \pi^p \). Clearly, \( \Omega(\pi^p) \cap \Omega^+(\pi^p) \) contains the open set \( \Omega(\pi^p) \cap \Omega^+(\pi^p) = \{ \omega : s^d(\omega) < \pi^p < s^p(\omega) \} \). If we this set is non-empty, we are done because \( G \) has full support. Both \( \Omega(\pi^p) \) and \( \Omega^+(\pi^p) \) are nonempty. Suppose that \( \Omega^+(\pi^p) \cap \Omega^+(\pi^p) = \emptyset \). Then, for every \( \omega \in \Omega^+(\pi^p) \), we have \( s^d(\omega) = \pi^p \) and that \( \Omega(\pi^p) \cap \Omega^+(\pi^p) = \{ \omega : s^p(\omega) = \pi^p \} \). Now, consider \( \omega \in \Omega(\pi^p) \) and any sequence \( \{ \omega_n \} \) in \( \Omega^+(\pi^p) \) converging to \( \omega \). We have that \( \lim_{\omega_n \to \omega} s^d(\omega_n) \geq \pi^p > s^d(\omega) \). But this violates the continuity of \( s^d \)—a contradiction.

Now consider \( f = \pi^p \). Using again Lemma 3, we have

\[
\Psi'((\pi^p)^-) = \int_{\Omega(\pi^p)} \tilde{U}'((\pi^p); \omega) dG = \int_{\Omega} \tilde{U}'((\pi^p); \omega) dG = -\int_{\Omega} \phi^-(\omega) dG,
\]

where \( \phi^-(\omega) > 0 \) for all \( \omega \) such that \( s^d(\omega) < \pi^p \). Therefore, \( \Psi'((\pi^p)^-) < 0 \).

\[
\Box
\]

Let \( E(\beta) \) be the set of optimal floors and \( u^*(y; r) \) the indirect utility of spending \( y \in [0, 1] \).

**Lemma 5.** \( E(\beta) \) is decreasing in \( \beta \) in the strong set order.\(^{25}\) The largest optimal \( f \) converges monotonically to \( \pi^p \) as \( \beta \uparrow 1 \). There exists \( \beta > 0 \) such that \( E(\beta) = \{ f \} \) for all \( \beta \leq \beta \), where \( f \) satisfies \( f < \pi^p \) and

\[
U(B_f) = \max_{f \in [s^d, \pi^p]} \int_{\Omega} [\theta u^*(1 - f; r) + v(f)] dG.
\]

**Proof.** Fix \( f \in [s^d, \pi^p] \). The set \( \Omega(f) \) in Lemma 3 depends on \( \beta \) via \( (c^d, s^d) \). By standard arguments, if \( \beta < \beta' < 1 \), then \( s^d(\omega; \beta) < s^d(\omega; \beta') \) for every \( \omega \) and hence \( \Omega(f; \beta') \subset \Omega(f; \beta) \). Also, \( \Omega^-(f) \subset \Omega(f; \beta) \) for every \( \beta < 1 \) because \( s^d(\omega; \beta) < s^p(\omega) \) for every \( \omega \). So, if \( \beta < \beta' < 1 \),

\[
\Psi'(f; \beta) - \Psi'(f; \beta') = \int_{\Omega(f; \beta) \setminus \Omega(f; \beta')} \phi^+(\omega) dG \geq 0,
\]

where the inequality uses (5). By standard results, \( E(\beta) \) decreases in the strong set order.

Define \( f(\beta) = \max \{ f : \omega \in E(\beta) \} \). Since \( f(\beta) \geq \pi^p \) for all \( \beta \) and \( f(\cdot) \) is decreasing, \( \lim_{\beta \downarrow 1} f(\beta) \) exists; denote it by \( f(1-) \). Clearly, \( f(1) = \pi^p \). Now suppose that \( f(1-) > f(1) \). By a similar argument, for any \( f > \pi^p \), \( \lim_{\beta \downarrow 1} \Psi(\beta; \beta) \) exists and equals \(-\int_{\Omega^-(f)} \phi(\omega) dG < 0 \). Therefore, for \( \beta \) close enough to 1, \( f(\beta) \geq f(1-) \) cannot be optimal—a contradiction which implies \( f(1-) = f(1) \).

\(^{24}\)It is easy to see that the optimal \( f \) satisfies \( f \leq \pi^p \). Suppose \( f \in (\pi^p, 1) \). Then, for all \( \omega \), self-1 chooses \( s(\omega) = f \) and \( c(\omega) = c^f(\omega) \). Take any \( f' < f \). Then, for every \( \omega \), \( f' = \zeta(\omega) f + (1 - \zeta(\omega)) s^p(\omega) \) for some \( \zeta(\omega) \in (0, 1) \). Therefore, for every \( \omega \), \( \tilde{U}(f'; \omega) > \tilde{U}(f; \omega) \) because \( \tilde{U}(s^p(\omega); \omega) > \tilde{U}(f; \omega) \) and \( \tilde{U}(1) \) is strictly concave. It follows that self-0's payoff is strictly lower under \( f' \) than under \( f \).

\(^{25}\)Given two sets \( E \) and \( E' \) in \( \mathbb{R} \), \( E \geq E' \) in the strong set order if, for every \( f \in E \) and \( f' \in E' \), \( \min \{ f, f' \} \in E' \) and \( \max \{ f, f' \} \in E \) (Milgrom Paul and Shannon Chris (1994)).
Note that $\bar{s}(\beta) = \max_\Omega s^d(s; \beta)$ falls monotonically to 0 as $\beta \downarrow 0$. Let $\beta = \max\{\beta \in [0, 1] : \bar{s}(\beta) \leq \bar{s}_p\}$, which is strictly positive because $\bar{s}_p > 0$. Then, $\bar{\Omega}(f) = \Omega$ for all $\beta \leq \beta$ and $f \in [\bar{s}_p, \bar{s}_p]$ and hence

$$\Psi(f; \beta) = \int_\Omega [\theta u(c^f(\omega); r) + v(f)]dG. \tag{6}$$

From the proof of Lemma 3, $u(c^f(\omega); r) = \tilde{u}(f; \omega)$ is strictly concave in $f$ for all $\omega$. Thus, the maximizer of (6) is unique. From the proof of Lemma 4, the derivative of (6) is negative at $\bar{s}_p$ and hence $f < \bar{s}_p$.

We now show that self-0 benefits from using only $b_i$.

**Lemma 6.** Fix $i$ and consider plans $B_{b_i}$ with $b_j = 1$ for all $j \neq i$ and $f = 0$. There exists $b_i < \max_\omega c_i^d(\omega) \equiv \bar{c}_i^d$ such that $\mathcal{U}(B_{b_i}) > \mathcal{U}(\tilde{F})$.

**Proof.** Fix $i = 1$ and any $b_1 \in (0, \bar{c}_1^d]$. Let $(c^{b_1}, s^{b_1})$ describe self-1’s choices under $B_{b_1}$ and

$$\Phi(b_1) = \int_\Omega [\theta u(c^{b_1}(\omega); r) + v(s^{b_1}(\omega))]dG.$$

Let $\Omega(b_1) = \{\omega : c_i^d(\omega) > b_1\}$. Since $c_i^d$ is continuous, $\Omega(b_1)$ is non-empty and open if $b_1 < \bar{c}_1$, and hence $G(\Omega(b_1)) > 0$. We have

$$\Phi(b_1) - \Phi(\bar{c}_1) = \int_{\Omega(b_1)} [\theta u(c^{b_1}(\omega); r) + v(s^{b_1}(\omega))] - [\theta u(c^d(\omega); r) + v(s^d(\omega))]dG$$

$$= (1 - \beta) \int_{\Omega(b_1)} \left[v(s^{b_1}(\omega)) - v(s^d(\omega))\right]dG$$

$$+ \int_{\Omega(b_1)} \left[\tilde{V}(c^{b_1}(\omega); \omega) - \tilde{V}(c_1^d(\omega); \omega)\right]dG,$$

where

$$\tilde{V}(b_1; \omega) = \max_{\{c, s\} \in \mathbb{R}_{\geq 0}^{n+1}, \sum_{j=1}^n c_j \leq 1, c_1 \leq b_1} \{\theta u(c; r) + \beta v(s)\}.$$

Clearly, $\tilde{V}(c_1^d(\omega); \omega) \geq \tilde{V}(b_1; \omega)$ for all $\omega$. From the first-order conditions of the Lagrangian defining $\tilde{V}(b_1; \omega)$, we have $\lambda_1(\omega; b_1) = \theta u_1(c_1^d(\omega); r_1) - \beta v'(s^{b_1}(\omega))$, where $\lambda_1(\omega; b_1)$ is the Lagrange multiplier for $c_1 \leq b_1$. Since $(c^{b_1}(\omega), s^{b_1}(\omega))$ is continuous in $b_1$ and $\omega$, so is $\lambda_1(\omega; b_1)$.

Again by Theorem 1, p. 222, of Luenberger David G. (1969), $\tilde{V}(b_1; \omega)$ exists for all $b_1$ and equals $\lambda_1(\omega; b_1)$. It follows that $\tilde{V}''(c_1^d(\omega); \omega) = 0$ for all $\omega$ by the definition of $(c^d, s^d)$. By the Mean Value Theorem (MVT), $\tilde{V}'(c_1^d(\omega); \omega) - \tilde{V}(c^{b_1}(\omega); \omega) = \tilde{V}'(\chi(\omega); \omega)(c_1^d(\omega) - c_1^d(\omega))$ and $v(s^{b_1}(\omega)) - v(s^d(\omega)) = v'(\xi(\omega))(s^{b_1}(\omega) - s^d(\omega))$, where $\chi(\omega) \in [c_1^d(\omega), c_1^d(\omega)]$ and $\xi(\omega) \in [s^d(\omega), s^{b_1}(\omega)]$.

Let $b_1^\varepsilon = \bar{c}_1 - \varepsilon$ for some $\varepsilon > 0$. Fix $\omega \in \Omega(b_1^\varepsilon)$ and, for now, drop the dependence on $\omega$. Recall that $s^{b_1} + \sum_i c_i = s^d + \sum_i c_i^d = 1$. Since $s^{b_1} > s^d$ for $\varepsilon > 0$ (Lemma 2), we can write

$$-\frac{c_1^d - c_1}{s^{b_1} - s^d} = 1 + \sum_{j \neq 1} \frac{c_j - c_j^d}{s_j^{b_1} - s^d}. \tag{7}$$

22
Now, for any $b_i^r$, the first-order condition $\beta v'(s) - \theta u^d_j(c_j; r_j) = 0$ must hold for every $j \neq 1$. Therefore, again by the MVT, for all $j \neq 1$

$$c_j^b - c_j^d = \frac{\beta [v'(s_i^b) - v'(s_i^d)]}{\theta u^d_j(\zeta_j; r_j)} \tag{8}$$

for some $\zeta \in [c_j^d, c_j^b]$. Now, since $v''$ is continuous, $v'(y) - v'(\hat{y}) \geq v''|y - \hat{y}|$ for every $y > \hat{y} \geq s_i^d$, where $\bar{u}'' = \min_{\xi \in [s_i^d, 1]} v''(\xi) < 0$. Therefore, using (7) and (8),

$$-\frac{c_i^b - c_i^d}{s_i^b - s_i^d} \geq 1 + \frac{1}{s_i^b - s_i^d} \sum_{j \neq 1} \frac{\beta}{\theta u^d_j(\zeta_j; r_j)} [v'(s_i^b) - v'(s_i^d)]$$

$$\leq 1 + \frac{1}{s_i^b - s_i^d} \sum_{j \neq 1} \frac{\beta v''}{\theta u^d_j(\zeta_j; r_j)} [s_i^b - s_i^d] \leq 1 + \frac{\beta v''}{\theta} \sum_{j \neq 1} \frac{1}{u^d_j},$$

where the first inequality uses $u^d_j < 0$ and $\bar{u}^d_j = \max_{\xi \in [s_i^d, 1], r_j \in [s_j, \overline{s_j}]} u^d_j(\xi; r_j) < 0$. Letting $K = \left[1 + \frac{\beta v''}{\theta} \sum_{j \neq 1} \frac{1}{u^d_j}\right]^{-1}$, it follows that $s_i^b(\omega) - s_i^d(\omega) \geq K \left[c_i^d(\omega) - c_i^b(\omega)\right]$ for every $\omega \in \Omega(b_i^r)$.

These observations imply that $\Phi(b_i^r) - \Phi(\overline{c}_i^d)$ is bounded below by

$$\int_{\Omega(b_i^r)} \left[ K(1 - \beta) v'(\xi(\omega)) - \tilde{V}'(\zeta(\omega); \omega) \right] (c_i^d(\omega) - c_i^b(\omega)) dG. \tag{9}$$

Since $v'$ is continuous and strictly positive everywhere and $\xi(\omega) \in [s_i^d, 1]$ with $s_i^d > 0$ for all $\omega \in \Omega(b_i^r)$, there exists a finite $\kappa > 0$ such that $v'(\xi(\omega)) \geq \kappa$ for all $\omega \in \Omega(b_i^r)$.

Next let $\overline{\Omega}(b_i^r) = \{\omega : c_i^d(\omega) \geq b_i^r\}$. By continuity of $c_i^d$, $\overline{\Omega}(\cdot)$ is a compact-valued and continuous correspondence. Note that $\tilde{V}'(\chi(\omega); \omega) = \tilde{V}'(c_i^d(\omega); \omega) = 0$ if $c_i^d(\omega) = b_i^r$. We have

$$\sup_{\omega \in \Omega(b_i^r)} \tilde{V}'(\chi(\omega); \omega) = \sup_{\omega \in \overline{\Omega}(b_i^r)} \tilde{V}'(\chi(\omega); \omega) \leq \max_{b_i^r \leq \zeta \leq \overline{c}_i^d, \omega \in \Omega(b_i^r)} \tilde{V}'(\zeta; \omega) \equiv \kappa(b_i^r).$$

Clearly, $\kappa(b_i^r) \geq 0$ for every $\varepsilon > 0$, $\kappa(b_i^r) \leq \kappa(b_i^r')$ for $\varepsilon' > \varepsilon > 0$, and $\lim_{\varepsilon \to 0} \kappa(b_i^r) = 0$ because $\kappa(\cdot)$ is continuous. Therefore, there exists $\varepsilon^* > 0$ such that $\kappa(b_i^r) < \kappa(1 - \beta)K$. It follows that for all $\varepsilon \in (0, \varepsilon^*)$, expression (9) is strictly positive, and hence $\Phi(b_i^r) > \Phi(\overline{c}_i^d)$.

\hfill \square

We can now complete the proof. By Lemma 5, $\overline{f}(\beta)$ falls monotonically to $s_i^p$ when $\beta \uparrow 1$. Also, for every $i = 1, \ldots, n$, $s_i^d(\overline{\theta}, \overline{\tau}, \underline{\tau}_i; \beta)$ rises monotonically to $s_i^p(\overline{\theta}, \overline{\tau}, \underline{\tau}_i; \beta)$ as $\beta \uparrow 1$. By Remark 1, $s_i^d(\overline{\theta}, \overline{\tau}, \underline{\tau}_i; \beta) > s_i^p$. Given this, define

$$\beta^* = \inf \{\beta \in (0, 1) : \overline{f}(\beta) < \max_{i} s_i^d(\overline{\theta}, \overline{\tau}, \underline{\tau}_i; \beta)\}.$$ 

Clearly, $\beta^* < 1$ and, for every $\beta > \beta^*$, we have $s_i^d(\overline{\theta}, \overline{\tau}, \underline{\tau}_i; \beta) > \overline{f}(\beta)$ for at least some $i = 1, \ldots, n$. Hereafter, fix $\beta > \beta^*$ and any $i$ that satisfies this last condition.

For $\varepsilon \geq 0$, consider $b_i^r = \overline{c}_i^d - \varepsilon$ as in Lemma 6, where $\overline{c}_i^d = c_i^d(\overline{\theta}, \overline{\tau}, \underline{\tau}_i)$ by Remark 1. Let $\Phi(b_i^r, \overline{f}(\beta))$ be self-0's payoff from adding $b_i^r$ to the existing $\overline{f}(\beta)$. We will show that there
exists $\varepsilon > 0$ such that $\Phi(b_i^*, \overline{f}(\beta)) > \Phi(b_i^0, \overline{f}(\beta)) = U(B_{\overline{T}(\beta)})$. To do so, for any $\varepsilon \geq 0$, let $(c^\varepsilon, s^\varepsilon)$ be self-1’s choice function under $(b_i^*, \overline{f}(\beta))$ and $\Omega(b_i^0) = \{\omega \in \Omega : c_i^\varepsilon(\omega) > b_i^0\}$. Then,

$$
\Phi(b_i^*, \overline{f}(\beta)) - \Phi(b_i^0, \overline{f}(\beta)) = \int_{\Omega(b_i^0)} \left\{ \left[ \theta u(c^\varepsilon(\omega); r) + v(s^\varepsilon(\omega)) \right] - \left[ \theta u(c^0(\omega); r) + v(s^0(\omega)) \right] \right\} dG.
$$

Note that, if there exists $\varepsilon > 0$ such that $(c^\varepsilon(\omega), s^\varepsilon(\omega)) = (c^d(\omega), s^d(\omega))$ for all $\omega \in \Omega(b_i^0)$ and $0 < \varepsilon < \pi$, then for such $\varepsilon$’s the previous difference equals $\Phi(b_i^0) - \Phi(\overline{c}^0)$. By the conclusion of that proof, there exists $\varepsilon^* \in (0, \pi)$ such that $\Phi(b_i^{\varepsilon^*}, \overline{f}(\beta)) > \Phi(b_i^0, \overline{f}(\beta))$.

Thus we only need to prove the existence of $\pi$. Let $\Omega(\overline{f}(\beta)) = \{\omega \in \Omega : s^d(\omega) \leq \overline{f}(\beta)\}$, which is compact by continuity of $s^d$. Define $\tilde{c}_i = \max_{\Omega(\overline{f}(\beta))} c_i^0(\omega)$. Since $s^d(\overline{\theta}, \overline{r}_i, \underline{r}_i) > \overline{f}(\beta)$, $(\overline{\theta}, \overline{r}_i, \underline{r}_i) \notin \Omega(\overline{f}(\beta))$ and hence $c_i^0(\overline{\theta}, \overline{r}_i, \underline{r}_i) = c_i^0(\overline{\theta}, \overline{r}_i, \underline{r}_i)$, where $c_i^0(\overline{\theta}, \overline{r}_i, \underline{r}_i) = \overline{c}_i^d$ by Remark 1. We must also have $\tilde{c}_i < c_i^d$: Indeed, for all $\omega \in \Omega(\overline{f}(\beta))$, optimality requires

$$
\theta u_i(c_i(\omega); r_i) = \beta v'f(\overline{f}(\beta)) + \lambda_0(\omega) > \beta v'(s^d(\overline{\theta}, \overline{r}_i, \underline{r}_i)) - \theta u_i(s_i^{d}(\overline{\theta}, \overline{r}_i),
$$

where $\lambda_0(\omega) \geq 0$ is the Lagrange multiplier for $s \geq \overline{f}(\beta)$. If $\omega$ is such that $c_i^0(\omega) > \tilde{c}_i$, then $\omega \notin \Omega(\overline{f}(\beta))$—otherwise it would contradict the definition of $\tilde{c}_i$—and hence $c_i^0(\omega) = c_i^d(\omega)$. Let $\pi = \overline{c}_i^d - \tilde{c}_i > 0$. By construction for $\varepsilon \in (0, \pi)$, $c_i^0(\omega) > b_i^0$ implies $c_i^0(\omega) = c_i^d(\omega)$, as desired.

6.3 Proof of Proposition 3 and Corollary 1

**Lemma 7.** For every $\beta \in (0, 1)$, if $B \in B$ is optimal, then $max \{f, 1 - \sum_{i=1}^{n} b_i \} \geq \min_{\omega \in \Omega} s^p(\omega)$.

**Proof.** Define $\sigma = \max \{f, 1 - \sum_{i=1}^{n} b_i \}$. Since $s(\omega) + \sum_{i=1}^{n} c_i(\omega) = 1$, $s(\omega) \geq \sigma$ for all $\omega$. Without loss of generality, we can let $\sigma = \min_{\Omega} s(\omega)$: If $\min_{\Omega} s(\omega) > \sigma$, we could raise $f$ to the level $\min_{\Omega} s(\omega)$ and nothing would change.

Now fix $\beta \in (0, 1)$. Suppose $B'$ is optimal, but $\sigma' < s^p$. Consider $B'' \in B$ equal to $B'$, except for $f'' = s^p$. Since $B'$ is convex and compact, the ensuing allocation $(c', s')$ is continuous in $\omega$. So, $\Omega(s^p) = \{\omega \in \Omega : s'(\omega) < s^p\}$ contains an open subset and $G(\Omega(s^p)) > 0$. Consider $\omega \in \Omega(s^p)$ and the problem of maximizing $\theta u_i(c; r) + v(s)$ for $(c, s) \in \mathbb{R}_{+}^{n+1}$ subject to $c_i \leq b_i'$ for $i = 1, \ldots, n$ and $s \leq f$. For any $f < s^p$, the latter must bind because, by the logic of Lemma 2, self-0 would want to save at least $s^p(\omega) \geq s^p$ if facing only $c_i \leq b_i'$ for $i = 1, \ldots, n$. Therefore, self-0’s payoff from this fictitious problem is strictly increasing in $f$ for $f < s^p$. When self-1 faces $B''$, the constraint $s \geq s^p$ must bind, so his allocation $(c''(\omega), s^p)$ solves $\max u_i(c; r)$ subject to $c \in \mathbb{R}_{+}^{n}, c_i \leq b_i'$, and $\sum_{i=1}^{n} c_i \leq 1 - s^p$. This allocation coincides with self-0’s allocation in the fictitious problem with $f = s^p$. Hence, in $\omega$, $(c''(\omega), s^p)$ is strictly better for self-0 than $(c''(\omega), s'(\omega))$. For all $\omega \in \Omega(s^p)$, self-0’s payoff is then strictly larger under $B''$ than $B'$. Since for $\omega \notin \Omega(s^p)$ self-1’s allocation is unchanged, $U(B'') > U(B')$—a contradiction.

\[\qed\]

Given Lemma 7, we now complete the proof of Proposition 3. We first show that there exists $\beta_{**} > 0$ such that, if $\beta < \beta_{**}$, then for any $B \in B$ with $\sigma \geq s^p$ the resulting allocation $(c, s)$ satisfies $s(\omega) = \sigma$ for all $\omega \in \Omega$. It is enough to show that $s(\overline{\theta}, \overline{r}_i, \underline{r}_i) = \sigma = \max_{\Omega} s(\omega)$ must equal $\sigma$. By strict concavity of $v$, $v'(\overline{\sigma}) \leq v'(s^p) < +\infty$ because $s^p > 0$. By considering the Lagrangian of self-1’s problem in $\omega = (\overline{\omega}, \overline{r}_i)$, we have that $(c(\omega), s(\omega))$ must satisfy $\beta v'(\overline{\sigma}) + \phi_0(\omega) + \gamma_i(\omega) = \theta u_i(c_i(\omega); r_i)$ for all $i = 1, \ldots, n$, where $\phi_0(\omega) \geq 0$ and $\gamma_i(\omega) \geq 0$ are the Lagrange multipliers.
for 𝑠 ≥ 𝑓 and 𝑐𝑖 ≤ 𝑏𝑖. For every 𝑖 = 1, . . . , 𝑛, since 𝑐𝑖(𝜔) ≤ 1 and 𝑢𝑖(·; 𝜔𝑖) is strictly concave, 𝑢𝑖(𝑐𝑖(𝜔); 𝜔𝑖) ≥ 𝑢𝑖(1; 𝜔𝑖) > 0. Now let

\[ \beta_{ss} = \min_{i} \frac{\theta u_i^t(1; \omega_i)}{v'(s^p)} > 0. \]  

(10)

Then, for every \( \beta < \beta_{ss} \), we have \( \beta v'(s(\omega)) < \theta u_i(\omega_i; r_i) \) for all \( i = 1, \ldots, n \). Therefore, \( \phi_i(\omega) + \gamma_i(\omega) > 0 \) for all \( i = 1, \ldots, n \). Hence, either \( \phi_i(\omega) > 0 \), in which case \( \sigma = f = \sigma \); or \( \gamma_i(\omega) > 0 \) for all \( i = 1, \ldots, n \), in which case \( \sigma = 1 - \sum_{i=1}^{n} c_i(\omega) = 1 - \sum_{i=1}^{n} b_i = \sigma \).

Finally, let \( \beta < \beta_{*} = \min\{\beta, \beta_{ss}\} \) where \( \beta > 0 \) was defined in Lemma 5. Let \( B^\beta \in B \) be an optimal plan for \( \beta \). By Lemma 7, \( \sigma^\beta \geq s^p \). The previous result then implies that \( U(B^\beta) = \int_{\Omega} [\theta u(c(\omega); r) + v(\sigma^\beta)]dG \). Hence,

\[ U(B^\beta) \leq \int_{\Omega} [\theta u(c^{\sigma^\beta}(\omega); r) + v(\sigma^\beta)]dG \leq \int_{\Omega} [\theta u(c^\beta(\omega); r) + v(\beta)]dG = U(B_\beta), \]

where the first inequality holds since \( u(c(\omega); r) \leq \max_{c \in \mathbb{R}^n_+, \sum_{i=1}^n c_i \leq \sigma^\beta} u(c; r) = u(c^{\sigma^\beta}(\omega); r) \) for all \( \omega \in \Omega \) and from the definition of \( \beta \) in Lemma 5. If \( B^\beta \) involves budgets that bind for a set \( \Omega' \) with \( G(\Omega') > 0 \), then \( u(c(\omega); r) < u(c^{\sigma^\beta}(\omega); r) \) for all \( \omega \in \Omega' \) and \( U(B^\beta) < U(B_\beta) \). Therefore, optimal plans can only use \( f \).

Finally, let \( \tilde{r}', \tilde{r}, \tilde{r}'', \tilde{r} \), and \( \tilde{r} \) satisfy the properties in Corollary 1. Then \( s' = s^p(\tilde{r}, \tilde{r}') \geq s^p(\tilde{r}, \tilde{r}) = s^p \) with strict inequality if \( \tilde{r} \neq \tilde{r}' \) (Remark 1). Similarly, for \( \beta \in (0, 1) \), \( \tilde{s}^p(\beta) = s^p(\tilde{r}, \tilde{r}'; \beta) \leq s^p(\tilde{r}, \tilde{r}'; \beta) = \tilde{s}^p(\beta) \) with strict inequality if \( \tilde{r}' \neq \tilde{r} \). The definition of \( \beta_{ss} \) in (10), the strict concavity of \( v \), and \( r_i' \geq r_i \) imply that \( \beta_{ss} > \beta_{ss} \). The definition of \( \beta \) in the proof of Lemma 5 and the fact that \( \tilde{s}^d \) is strictly increasing in \( \beta \) imply that \( \beta_{ss} > \beta_{*} \). Therefore \( \beta_{*} > \beta_{ss} \).

6.4 Proof of Proposition 4

The proof is constructive: It first establishes the claimed properties for the illustrative three-state setting in Section 3.4, which are then used for the general result.

Part 1. Let \( \omega^0 = (\tilde{r}, \tilde{r}_1, \tilde{r}_2) \), \( \omega^1 = (\tilde{r}, \tilde{r}_1, \tilde{r}_2) \), and \( \omega^2 = (\tilde{r}, \tilde{r}_1, \tilde{r}_2) \) with respective probabilities \( g, \frac{1-g}{2}, \) and \( \frac{1-g}{2} \). Choose \( \beta < 1 \) so that \( s^d(\omega^1) = s^d(\omega^2) > s^p(\omega^0) \) and \( \theta \) so that \( c^p_0(\omega^1) > c^p_0(\omega^0) \) and \( c^p_2(\omega^2) > c^p_2(\omega^0) \).

Lemma 8. There exists \( g^* \in (0, 1) \) such that, if \( g > g^* \), then the optimal \( B \in B \) satisfies \( f = s^p(\omega^0) \), \( b_1 = c^p_0(\omega^1) \), and \( b_2 = c^p_2(\omega^2) \).

Existence of an optimal \( B \) follows from an argument similar to the proof of the Existence Lemma in the Online Appendix. Claims 1–5 characterize its properties.

Claim 1. There exists \( g^* \in (0, 1) \) such that, if \( g > g^* \) and self-0 can use only \( f \), she sets \( f = s^p(\omega^0) \).

Proof. We can focus on \( f \in [s^d(\omega^1), s^p(\omega^1)] \cup \{s^p(\omega^0)\} \). For simplicity, let \( U(c, s; \omega) = \theta u(c; r) + v(s) \). If \( f = s^p(\omega^0) \), by symmetry self-0’s payoff is \( gU(c^p(\omega^0), s^p(\omega^0); \omega^0) + (1 - g)U(c^d(\omega^1), s^d(\omega^1); \omega^1) \); if instead \( f \in [s^d(\omega^1), s^p(\omega^1)] \), self-0’s payoff is \( gU(c^f(\omega^0), f; \omega^0) + (1 - g)U(c^f(\omega^0), f; \omega^0) \) with

\[ 25 \]
\[ g)U(c^f(\omega^1), f; \omega^1) \]

where \( c^f(\omega) \) is defined in Lemma 3. Thus, \( f = s^p(\omega^0) \) identifies the best \( B \) that uses only \( f \) if

\[
\frac{g}{1 - g} > \max_{f \in [s^d(\omega^1), s^p(\omega^1)]} \frac{U(c^f(\omega^1), f; \omega^1) - U(c^d(\omega^1), s^d(\omega^1); \omega^1)}{U(c^p(\omega^0), s^p(\omega^0); \omega^0) - U(c^f(\omega^0), f; \omega^0)} \geq 0. \tag{11}
\]

The term on the right-hand side is well defined; also, for all \( f \in [s^d(\omega^1), s^p(\omega^1)] \) we have

\[
U(c^p(\omega^1), s^p(\omega^1); \omega^1) \geq U(c^f(\omega^1), f; \omega^1) \geq U(c^d(\omega^1), s^d(\omega^1); \omega^1) \text{ and } U(c^p(\omega^0), s^p(\omega^0); \omega^0) > U(c^f(\omega^0), f; \omega^0) \] because \( s^d(\omega^1) > s^p(\omega^0) \).

Proof. Claim 2. Fix \( i \in \{1, 2\} \). Suppose self-0 knows that the state is \( \omega^i \) and can only use \( b_i \). Then, \( b_i = c^i_1(\omega^i) \) is optimal.

Proof. Let \( i = 1 \). The argument in the proof of Lemma 6 implies that it is optimal to set

\[
b_1 < c^1_1(\omega^1).
\]

To find the optimal \( b_1 \), consider first self-1’s problem to maximize \( \theta|x|\ln(c_1) + r\ln(c_2) + \beta \ln(s) \) subject to \( s + c_1 + c_2 \leq 1 \) and \( c_1 \leq b_1 \). Since both constraints must bind, this becomes \( \max_{s \in [0, 1]} \{ \theta r \ln(1 - b_1 - s) + \beta \ln(s) \} \). The solution is characterized by the first-order conditions, which lead to

\[
s(b_1) = \frac{\beta}{\theta \tau + \beta} (1 - b_1) \quad \text{and} \quad c_2(b_1) = \frac{\theta x}{\theta \tau + \beta} (1 - b_1).
\]

Given this, self-0’s payoff in \( \omega^1 \) as a function of \( b_1 \) becomes (up to a constant)

\[
\theta|x|\ln(b_1) + r \ln(1 - b_1)) + \ln(1 - b_1). \tag{12}
\]

The optimal \( b_1 \) is again characterized by the first-order condition, which leads to

\[
b_1 = \frac{\theta x}{1 + \theta \tau + \theta |x|}. \tag{13}
\]

Finally, \( c^p_1(\omega^1) \) results from maximizing \( \theta|x|\ln(c_1) + r\ln(c_2) + \beta \ln(s) \) subject to \( s + c_1 + c_2 \leq 1 \). Substituting \( s = 1 - c_1 - c_2 \) and combining the first-order conditions yields

\[
c^p_1(\omega^1) = \frac{\theta x}{1 + \theta \tau + \theta |x|}. \tag{14}
\]

Proof. Let \( i = 1 \). Similar calculations to the proof of Claim 2 imply that if self-0 can impose only \( b_2 \), she sets

\[
b_2 = \frac{\theta x}{1 + \theta \tau + \theta |x|}.
\]
We want to argue that self-0’s payoff in $\omega^1$ is strictly larger if she uses only $b_1$ as in (13) than if she uses only $b_2$ as in (14). Substituting the choices implied by $b_1$ and $b_2$ into self-0’s utility function, one can show that $b_1$ in (13) is strictly better than $b_2$ in (14) if and only if

$$(1 + \theta r) \ln(\beta + \theta r) - (1 + \theta r) \ln(\beta + \theta r) > (1 + \theta r) \ln(1 + \theta r) - (1 + \theta r) \ln(1 + \theta r).$$

To show that this holds, consider $\varphi(\beta, r) = (1 + \theta r) \ln(\beta + \theta r)$ for $0 < \beta < 1$ and $r > 0$. Since

$$\varphi_{\beta r}(\beta, r) = \frac{\partial}{\partial r} \left( \frac{1 + \theta r}{\beta + \theta r} \right) = \frac{\theta(\beta - 1)}{(\beta + \theta r)^2} < 0,$$

$\varphi(\beta, r) - \varphi(\beta, r)$ is strictly decreasing in $\beta$. Continuity gives the result.

\[ \square \]

**Claim 4.** If $B$ is optimal, then $f$ can bind at most in $\omega^0$.

**Proof.** If $f$ binds in all $\omega$s, then $B$ is weakly dominated by a policy using only $f$ and no budgets, as they distort $c$ without raising $s$. Given $g > g^*$, by Claim 1 the latter plan is strictly dominated by one using only $f = s^p(\omega^0)$. Clearly, if $f$ binds in $\omega^1$ and $\omega^2$, it must bind in $\omega^0$.

Now suppose that $f$ binds only in $\omega^0$ and another state, say, $\omega^1$. There are two cases:

**Case 1:** $b_1$ does not bind in $\omega^2$. Then, removing $b_1$ leads to a weakly superior policy in which $f$ binds only in $\omega^0$ and $\omega^1$. Given $g > g^*$, however, the gain from raising $f$ above $s^p(\omega^0)$ to improve self-1’s allocation only in $\omega^1$ does not justify the loss created in $\omega^0$. Therefore, $B$ is again strictly dominated by the policy obtained if we remove $b_1$ and set $f = s^p(\omega^0)$.

**Case 2:** $b_1$ binds also in $\omega^2$. This implies that $f$ has to bind in all $\omega$s. Indeed, since $b_1$ binds in both $\omega^1$ and $\omega^2$, self-1 chooses $c_1 = b_1$ in both states; also, since in $\omega^2$ good 2 is more valuable than in $\omega^1$, self-1 wants to allocate more income to good 2 than to $s$ relative to $\omega^1$, and so $f$ also binds in $\omega^2$. But we know that such a policy is strictly dominated by using only $f = s^p(\omega^0)$.

\[ \square \]

**Claim 5.** If $B$ involves binding budgets, then $b_i$ can bind at most in $\omega^i$ for $i = 1, 2$.

**Proof.** Without loss, consider $b_1$. Suppose first that $b_1$ binds in all states, which implies that $c_1(\omega^i) = b_1$ for all $i = 0, 1, 2$. There are five cases to consider:

**Case 1:** Neither $b_2$ nor $f$ bind in any state. Since $\overline{\theta} > \theta$, $c_2(\omega^0) > c_2(\omega^2)$. The plan cannot be optimal because, given $b_1$, self-0 would be strictly better off by adding an $f$ that binds only in $\omega^0$: Even if $b_1$ were binding for self-0 in $\omega^0$, she would strictly prefer $c_2 < c_2(\omega^0)$ of good 2.

**Case 2:** $b_2$ binds in all states. Then, $c_2(\omega^i) = b_2$ and $s(\omega^i) = 1 - b_1 - b_2$ for all $i = 0, 1, 2$. This plan is strictly dominated by one that imposes only $f = 1 - b_1 - b_2$—because budgets are distorting—which is in turn strictly dominated by the plan with only $f = s^p(\omega^0)$ given $g > g^*$.

**Case 3:** $b_2$ binds in no state. Then, as in case 1, for $B$ to be optimal $f$ must bind at least in $\omega^0$ and only in $\omega^0$ by Claim 4. Since by assumption $b_1$ binds in all states, it must be that $b_1 < c_2^0(\omega^1)$. Indeed, if $b_1 \geq c_2^0(\omega^1)$, the optimal $f$ equals $s^p(\omega^0)$; since by assumption $c_2^0(\omega^0) < c_2^0(\omega^1)$, $b_1$ cannot bind in $\omega^0$. It follows that, with regard to $\omega^0$ and $\omega^1$, self-0 would be strictly better off replacing $b_1$ and $f$ with $\tilde{b}_1 = c_2^0(\omega^1)$ and $\tilde{f} = s^p(\omega^0)$. With regard to $\omega^2$, self-0 would be better off by replacing $b_2$ with $\tilde{b}_2 = c_2^2(\omega^2)$: By Claim 3, even if $b_1$ were perfectly tailored for $\omega^2$, it would be strictly dominated in $\omega^2$ by $\tilde{b}_2$.

**Case 4:** $b_2$ binds only in $\omega^0$. Since self-1’s choices satisfy $c_2(\omega^0) > c_2(\omega^2)$ if the plan used only
b_1$, it follows that self-0 can obtain in all $\omega$s the same allocations induced by $B$ if she uses an $f$ that binds only in $\omega^0$. Such a plan, however, is again strictly dominated as in case 3.

Case 5: $b_2$ binds in $\omega_1$ and in $\omega^2$. Since self-1’s choices satisfy $c_2(\omega^0) > c_2(\omega^2)$ if the plan used only $b_1$, self-0 could again obtain the same allocation in all $\omega$s with an $f$ that binds only in $\omega^0$ and $\omega^2$. By Claim 4, however, such a plan cannot be optimal.

Now suppose $b_1$ binds in only two states. If these are $\omega_1$ and $\omega^0$, by the same argument as in case 3 above self-0 is strictly better off by replacing $b_1$ and $f$ with $\bar{b}_1 = c_1^f(\omega^1)$ and $\bar{f} = s^{p^*}(\omega^0)$ as well as $b_2$ with $\bar{b}_2 = c_2^f(\omega^2)$. If $b_1$ binds in $\omega_1$ and $\omega^2$, it must also bind in $\omega^0$—which is the case we considered before. Indeed, if $b_1$ binds in $\omega^2$, then it will also bind at the fictitious state $(\theta, \tau, \tau)$ and hence in $\omega^0$ where both goods are more valuable. Lastly, $b_1$ cannot bind only in $\omega^0$ and $\omega^2$: It would have to bind also in $\omega_1$, since in $\omega_1$ good 1 is more valuable than in $\omega^2$.

Finally, suppose $b_1$ binds in only one $\omega$. We have just argued that if $b_1$ binds in $\omega^2$, it must also bind in $\omega^1$. Thus, we have to rule out the case where $b_1$ binds only in $\omega^0$. This is possible only if in $\omega^0$ also $b_2$ binds, inducing self-1 to overconsume good 1. However, such a $b_2$ must also bind in $\omega^2$, but we just showed that a $b_1$ cannot bind in more than one $\omega$.

\[ \square \]

Part II. The three-state setting can be modified so that the optimal $B$ uses only $b_1$ and $b_2$. Fix $g > g^*$ and the other parameters, except $\bar{g}$. Raise $\bar{g}$ to $\bar{g}'$ so that $c_i^p(\omega^0) > c_i^p(\omega^1)$ for $i = 1, 2$.

**Lemma 9.** There exists $\bar{g}'$ such that in the optimal $B \in \mathcal{B}$ both $b_1$ and $b_2$ bind, but $f$ never binds. In particular, the optimal $B$ satisfies $b_1 = b_2$ and $c_i^p(\omega^1) < b_i < c_i^p(\omega^0)$ for $i = 1, 2$.

Start from $\bar{g}$ that implies $c_i^p(\omega^1) > c_i^p(\omega^0)$ for $i = 1, 2$ and hence leads to the optimal $B$ in Lemma 8. If we raise $\bar{g}$, $c_i^p(\omega^0)$ and $c_i^p(\omega^1)$ rise continuously while always satisfying $c_i^p(\omega^0) = c_i^p(\omega^1)$. There exists a unique $\bar{g}'$ such that, when $\bar{g} = \bar{g}'$, $c_i^p(\omega^1) = c_i^p(\omega^0)$ for $i = 1, 2$.

For $\bar{g} \leq \bar{g}'$, the optimal $B$ remains $b_1 = c_1^f(\omega^1)$, $b_2 = c_2^f(\omega^2)$, and $f = s^{p^*}(\omega^0)$, where the latter falls continuously as $\bar{g}$ rises towards $\bar{g}'$.

Now, let $\mathcal{B}(\bar{g}) \subset \mathcal{B}$ be the set of optimal $B$s as a function of $\bar{g}$. By the previous argument, $\mathcal{B}(\bar{g})$ is singleton for $\bar{g} \leq \bar{g}'$. Define the distance between any $B$ and $B'$ as the Euclidean distance between $(f, b_1, b_2)$ describing $B$ and $(f', b_1', b_2')$ describing $B'$. By the Maximum Theorem, $\mathcal{B}(\bar{g})$ is upper hemi-continuous in $\bar{g}$.

By choosing $\bar{g} > \bar{g}'$ sufficiently close to $\bar{g}'$, we can make the distance between $B(\bar{g})$ and every $B \in \mathcal{B}(\bar{g})$ arbitrarily small. There exists $\varepsilon > 0$ such that, if $\bar{g} \in (\bar{g}', \bar{g}' + \varepsilon)$, for every $B \in \mathcal{B}(\bar{g})$ we have (1) $b_i(\bar{g}) < c_i^f(\omega^i)$ for $i = 1, 2$ and (2) $f(\bar{g})$ can bind neither in $\omega^1$ nor in $\omega^2$. To see (2), note that $\mathcal{B}(\bar{g}')$ contains the plan defined by $b_i(\bar{g}') = c_i^f(\omega^i)$ for $i = 1, 2$ and $f(\bar{g}') = s^{p^*}(\omega^0)$, where $f(\bar{g}') = 1 - b_1(\bar{g}') - b_2(\bar{g}')$ and hence $f$ is redundant. Thus, $\mathcal{B}(\bar{g})$ contains no plan with $f(\bar{g}) > 1 - b_1(\bar{g}) - b_2(\bar{g})$, as such plans are strictly dominated for the same argument that rules them out in the proof of Lemma 8. Since the largest value of $f(\bar{g})$ must be close to $f(\bar{g}')$ for $\bar{g} \in (\bar{g}', \bar{g}' + \varepsilon)$, $f(\bar{g})$ cannot bind in $\omega^1$ and $\omega^2$ as well.

Fix $\bar{g} \in (\bar{g}', \bar{g}' + \varepsilon)$. Claims 6–9 characterize the properties of every $B \in \mathcal{B}(\bar{g})$.

---

26 Although self-0’s and self-1’s utility functions are not continuous at the boundary of $\mathbb{R}_+^2$ due to their logarithmic form, this is irrelevant because it is never optimal to choose $B$ that forces 0 allocation to some dimension. Formally, there exists $\varepsilon > 0$ such that, if we required $f \leq 1 - \varepsilon$ and $b_i \geq \varepsilon$ for all $i = 1, 2$, we would never affect self-0’s problem.
Claim 6. For every $B \in \mathcal{B}(\overline{b})$, $b_1(\overline{b})$ and $b_2(\overline{b})$ must bind in $\omega^0$—that is, $c_i(\omega^0) = b_i(\overline{b})$ for $i = 1, 2$. Given this, $s(\omega^0) = 1 - b_1(\overline{b}) - b_2(\overline{b})$ and hence $f$ can be removed.

Proof. Note that self-0’s objective in $\omega^i$ as a function of $b_i$ is strictly concave and decreasing for $b_i > c_i^p(\omega^i)$ (see (12)). Thus, if for example $b_1(\overline{b})$ is not binding for self-1 in $\omega^0$—that is, $b_1(\overline{b}) > c_1(\omega^0)$—self-0 can lower $b_1$ without affecting self-1’s choice in $\omega^0$ and $\omega^2$ and strictly improve her payoff in $\omega^1$. Hence, the initial plan would not be optimal.

Claim 7. $b_1(\overline{b}) = b_2(\overline{b})$ for every $B \in \mathcal{B}(\overline{b})$.

Proof. Without loss, suppose $b_1(\overline{b}) > b_2(\overline{b})$. Note that $b_2(\overline{b}) < c_2^p(\omega^0)$ because, otherwise, we would have $b_1(\overline{b}) > c_1^p(\omega^0) = c_2^p(\omega^0)$, contradicting the previous claim. Consider the alternative with $b_1^\varepsilon = b_1(\overline{b}) - \varepsilon$ and $b_2^\varepsilon = b_2(\overline{b}) + \varepsilon$ for $\varepsilon > 0$. For $\varepsilon$ small, $b_1^\varepsilon$ and $b_2^\varepsilon$ continue to bind in $\omega^0$, so $1 - b_1^\varepsilon - b_2^\varepsilon = s(\omega^0)$. In $\omega^0$, self-0’s payoff is higher, because given $s(\omega^0)$ the chosen $c$ is closer to being symmetric and hence to the best one according to self-0’s preference. Due to symmetry and the strict concavity in self-0’s payoff induced by $b_1$ in $\omega^i$ for $i = 1, 2$ (see (12)), the decrease in the her payoff in $\omega^2$ resulting from the slacker $b_2$ is more than compensated by the increase in $\omega^1$ resulting from the tighter $b_1$. Hence, overall self-0’s payoff is strictly larger with $(b_1^\varepsilon, b_2^\varepsilon)$ than with $(b_1(\overline{b}), b_2(\overline{b}))$, contradicting the optimality of the latter plan.

Claim 8. $1 - b_1(\overline{b}) - b_2(\overline{b}) > s^p(\omega^0)$ for every $B \in \mathcal{B}(\overline{b})$.

Proof. If $1 - b_1(\overline{b}) - b_2(\overline{b}) < s^p(\omega^0)$, self-0 can set $f = s^p(\omega^0)$ and get a strictly higher payoff in $\omega^0$ without affecting self-1’s choices in $\omega^1$ and $\omega^2$. If $1 - b_1(\overline{b}) - b_2(\overline{b}) = s^p(\omega^0)$, then $b_i = c_i^p(\omega^0)$ for $i = 1, 2$ and so $(c(\omega^0), s(\omega^0)) = (c^p(\omega^0), s^p(\omega^0))$. Therefore, it would be possible to lower both $b_1(\overline{b})$ and $b_2(\overline{b})$ by the same small $\varepsilon$, in order to induce a first-order gain in self-0’s payoff in $\omega^1$ and $\omega^2$ because $b_i(\overline{b}) > c_i^p(\omega^i)$ for $i = 1, 2$, while causing only a second-order loss in $\omega^0$.

Claim 9. All $B \in \mathcal{B}(\overline{b})$ have the same $b_1$ and $b_2$ and satisfies the properties in Lemma 9.

Proof. Let $b_1 = b_2 = b$. Self-0’s payoff in $\omega^1$ and $\omega^2$ is given by (12) up to a constant: $\theta [\pi \ln(b) + \pi \ln(1 - b)] + \ln(1 - b)$. Her payoff in $\omega^0$ is given, up to a constant, by $2\theta \pi \ln(b) + \ln(1 - 2b)$. Therefore, self-0’s expected payoff from $b$ is strictly concave. To see that $c_i^p(\omega^i) > b_i > c_i^p(\omega^0)$ for $i = 1, 2$, consider the following. A $b_i > c_i^p(\omega^i)$ is strictly dominated by $b_i = c_i^p(\omega^i)$ for every $i$, as this is the optimal level of $b_i$ in $\omega^i$. Consequently, we must have $b_i < c_i^p(\omega^i)$, because by assumption $1 - c_1(\omega^1) - c_2(\omega^2) > s^p(\omega^0)$ for $\overline{b} > \overline{b}^\dagger$ and so reducing $b_i$ below $c_i^p(\omega^i)$ by the same small amount for $i = 1, 2$ causes a first-order gain in $\omega^0$ and a second-order loss in $\omega^1$ and $\omega^2$.

Part III. Let $G^{fb}$ be a distribution over $(\omega^0, \omega^1, \omega^2)$ that leads to Lemma 8 and $\overline{C}$ the uniform over $[\overline{b}, \overline{b}] \times [r, \tau]^2$. Let $C^{fb}$ be a distribution that leads to Lemma 9 and $\overline{C}'$ the uniform over $[\overline{b}, \overline{b}'] \times [r, \tau]^2$, where $\overline{b}'$ is as in Lemma 9. For $\alpha \in [0, 1]$, let $G^{fb}_\alpha = \alpha G^{fb} + (1 - \alpha)\overline{C}$ and $G^{b}_\alpha = \alpha G^{fb} + (1 - \alpha)\overline{C}'$. Proposition 4 follows from the next result.
Corollary 2. (1) There exists $\alpha \in (0, 1)$ such that, given $G^h_\alpha^f$, $f$, $b_1$, and $b_2$ are all binding for every optimal $B$. (2) There exists $\alpha' \in (0, 1)$ such that, given $G^b_\alpha^f$, for every optimal $B$ both $b_1$ and $b_2$ bind, but $f$ never binds.

Proof. Let $B_f \subset B$ contain all Bs that can use only $f$, $B_b$ all Bs that can use both $b_1$ and $b_2$, and $B_{b_i}$ all Bs that can use only $b_i$ for $i = 1, 2$. To indicate that self-0's expected payoff is computed using some distribution $\tilde{G}$, we will use the notation $\mathcal{U}(B; \tilde{G})$.

Part (1): For every $B$ and $\alpha \in [0, 1]$, $\mathcal{U}(B; G^b_\alpha) = \alpha \mathcal{U}(B; G^h_\alpha) + (1 - \alpha) \mathcal{U}(B; \tilde{G})$. Now define $W^B_f(\alpha) = \max_{B \in B_f} \mathcal{U}(B; G^h_\alpha)$ and $W^B_b(\alpha) = \max_{B \in B_b} \mathcal{U}(B; G^b_\alpha)$, $\alpha \in [0, 1]$.

Both $W^B_f$ and $W^B_b$ are well defined by the same argument of the Existence Lemma in the Online Appendix and continuous functions of $\alpha$ by the Maximum Theorem. Let $B^B_f$ denote the optimal plan in Lemma 8. Note that $\mathcal{U}(B^B_f; \tilde{G})$ is finite since self-1's resulting choices are bounded away from 0 in all dimensions. We have that $\lim_{\alpha \to 1} \mathcal{U}(B^B_f; G^b_\alpha^f) - W^B_b(\alpha) > 0$ for both $j = f$ and $j = b$. Therefore, there exists $\hat{\alpha} \in (0, 1)$ such that $B^B_f$ strictly dominates every $B \in B_f \cup B_b$ given $G^b_\alpha$.

Part (2): For every $B$ and $\alpha \in [0, 1]$, $\mathcal{U}(B; G^b_\alpha) = \alpha \mathcal{U}(B; G^h_\alpha) + (1 - \alpha) \mathcal{U}(B; \tilde{G})$. Let $B^B$ denote the optimal plan in Lemma 9. By the same logic of the proof of Part (1), there exists $\alpha'' \in (0, 1)$ such that, for $\alpha \in (\alpha'', 1)$, $B^B$ strictly dominates every $B \in B_f \cup B_b \cup B_{b_1} \cup B_{b_2}$ given $G^b_\alpha$. It remains to show that there exists $\alpha' \in (\alpha'', 1)$ such that $B^B$ strictly dominates every $B \in B$ given $G^b_\alpha$. To this end, define $B(\alpha) = \arg \max_{B \in B} \mathcal{U}(B; G^b_\alpha)$. $B(\cdot)$ is upper hemicontinuous by the Maximum Theorem. Note that $B(1)$ is characterized by $(f^*, b_1^*, b_2^*)$ such that $b_1^*$ and $b_2^*$ are unique and satisfy Lemma 9, and $f^* \in [0, \bar{f}]$ where $\bar{f} = 1 - b_1^* - b_2^*$. For every $\eta > 0$, there exists $\varepsilon > 0$ such that, if $\alpha \in (1 - \varepsilon, 1)$, then $f \in [0, \bar{f} + \eta]$, $b_1 \in (b_1^* - \eta, b_1^* + \eta)$, and $b_2 \in (b_2^* - \eta, b_2^* + \eta)$ for every $(f, b_1, b_2)$ corresponding to some $B \in B(\alpha)$. Choosing $\eta$ small enough ensures that for all $B \in B(\alpha)$ we have (1) $1 - b_1 - b_2 > s^b(\omega^0)$, (2) removing $f$ leads to a plan such that $b_1$ and $b_2$ bind in $\omega^0$, and (3) $f$ cannot bind in $\omega^1$ and $\omega^2$, as self-1's choice of $s$ strictly exceeds $\bar{f}$ in $\omega^1$ and $\omega^2$ under all $B \in B(1)$.

Take any $B \in B(\alpha)$ and fix its $b_1$ and $b_2$. The $f$ completing $B$ must be optimally chosen given $b_1$ and $b_2$. We claim that it must satisfy $f \leq 1 - b_1 - b_2 = \bar{f}$ for $\alpha$ sufficiently close to 1. Suppose not. Consider self-0's expected gain from imposing $f > \bar{f}$. The gain in $\omega^0$ is

$$ (1 - \beta)[v(f) - v(\bar{f})] + \bar{V}(f; \omega^0) - \bar{V}(\bar{f}; \omega^0),$$

and the expected gain under the distribution $\tilde{G}'$ is

$$ \int_{\Omega(\bar{f})} \{(1 - \beta)[v(f) - v(\bar{s}(\omega))] + \bar{V}(f; \omega) - \bar{V}(\bar{s}(\omega); \omega)\} d\tilde{G}',$$

where $\Omega(f) \subset \Omega' = [\theta, \bar{\theta}] \times [\bar{r}, \bar{r}]$ is the set of states in which $f$ affects self-1's choices, $(\bar{c}, \bar{s})$ is self-1's allocation function under the policy using only $b_1$ and $b_2$, and

$$ \bar{V}(k; \omega) = \max_{\{\bar{c}, \bar{s}\} \in B, \bar{c}_1 \leq \bar{c}_2, \bar{s}_1 \leq \bar{s}_2, \bar{s}_2 \geq \bar{k}} \{\theta v(\bar{c}; \bar{r}) + \beta v(\bar{s})\}, \quad k \in [\bar{k}, 1], \omega \in \Omega'. $$

\footnote{Recall Footnote 26.}
Since $\nabla(f; \omega) \leq \nabla(\hat{s}(\omega); \omega)$ and $\hat{s}(\omega) \geq \bar{k}$ for all $\omega \in \Omega$, for all $f \geq \bar{k}$, (16) is bounded above by

$$\int_{\Omega(f)} (1 - \beta)[v(f) - v(\hat{s}(\omega))] dG' \leq (1 - \beta)[v(f) - v(\bar{k})].$$

Note that the right-hand side of this expression depends on $\alpha$ only via $\bar{k}$.

Now focus on $\nabla(k; \omega^0)$. For every $f > \bar{k}$, (1) $f$ always binds, because $\bar{k} > s^*(\omega^0)$ and hence self-1 wants to choose $s < f$; (2) only one $b_i$ can bind, because if both bind, then $s(\omega^0) = \bar{k} < f$, which is impossible; (3) one $b_i$ never binds, because goods are normal, so for all $f > \bar{k}$ self-1’s chooses $c_i(\omega^0) < b_i$ for at least one $i = 1, 2$. Without loss, suppose that $b_2$ never binds. If we remove $b_2$, $\nabla(k; \omega^0)$ equals self-1’s indirect utility under the plan defined by $k \in [\bar{k}, 1]$ and $b_1$ only, denoted by $\nabla(k; \omega^0, b_1)$. By the same argument of Lemma 3, $\nabla(k; \omega^0, b_1)$ is continuously differentiable in $k$ for $k \in (0, 1]$ and $\nabla'(k; \omega^0, b_1) = -\lambda(\omega^0; k)$, where $\lambda(\omega^0; k)$ is the Lagrange multiplier associated to $s \geq k$. Using the Lagrangian defining $\nabla(k; \omega^0, b_1)$, we have $\lambda(\omega^0; k) = \bar{\theta} u^2_2(c_2(\omega^0; k); \bar{\theta}) - \beta v'(k)$. Note that $\lambda(\omega^0; k) > 0$ for all $k \in [\bar{k}, 1]$, because such floor levels must always bind for self-1. Moreover, $\lambda(\omega^0; k)$ is strictly increasing in $k \in [\bar{k}, 1]$ because $v$ is strictly concave, $u^2_2 < 0$, and $c_2(\omega^0; k)$ is non-increasing in $k$ by normality of goods. Therefore, $\nabla'(k; \omega^0) = -\lambda(\omega^0; k)$ for all $k \in [\bar{k}, 1]$ and $\nabla'(\bar{k}; \omega^0) = -\lambda(\omega^0; \bar{k})$, where the plus denotes the right derivative.\footnote{\n$\nabla(k; \omega^0)$ is not differentiable at $k = \bar{k}$, as $\nabla(k; \omega^0)$ is constant for $k < \bar{k}$ and $\nabla'(\bar{k}; \omega^0) = 0$.}

Moreover, $\nabla'(k; \omega^0)$ is strictly decreasing in $k$.

Observe that

$$(1 - \beta) v'(\bar{k}) + \nabla'(\bar{k}; \omega^0) = v'(\bar{k}) - \bar{\theta} u^2_2(c_2(\omega^0; \bar{k}); \bar{\theta}),$$

which is strictly negative. This is because $b_1 < c^*_1(\omega^0)$ and $b_2 < c^*_2(\omega^0)$ by Lemma 9 since $\alpha$ is close to 1, which implies that $b_1$ and $b_2$ must bind for self-0; consequently, $f = \bar{k}$ and $b_1$ must also bind for self-0. The right-hand side of (17) coincides with the negative of the Lagrange multiplier associated with $s \geq \bar{k}$ in self-0’s problem that also includes $c_1 \leq b_1$.

Recall that $\bar{k}$ depends on $\alpha$—hence denote it by $\bar{k}_\alpha$—and consider

$$g\nabla(\bar{k}_\alpha; \omega^0) + [\alpha g + (1 - \alpha)](1 - \beta) v'(\bar{k}_\alpha).$$

This is strictly negative for $\alpha = 1$, in which case $\bar{k}_1 = 1 - b^*_1 - b^*_2$. By continuity of (18) in $(\alpha, k)$ and upper hemi-continuity of $\mathcal{B}(\alpha)$, there exists $\varepsilon > 0$ such that (18) is strictly negative for $\alpha \in (1 - \varepsilon, 1]$. By the monotonicity of $v'$ and $\nabla'(\cdot; \omega^0)$, (18) is strictly decreasing for $k \geq \bar{k}_\alpha$.

Finally, for every $\alpha \in (1 - \varepsilon, 1]$ and $f > \bar{k}_\alpha$,

$$\int_{\bar{k}_\alpha}^f \left\{[\alpha g + (1 - \alpha)](1 - \beta) v'(k) + g\nabla(k; \omega^0) - \nabla(\bar{k}_\alpha; \omega^0)\right\} dk$$

$$< \left\{[\alpha g + (1 - \alpha)](1 - \beta) v'(\bar{k}_\alpha) + g\nabla'(\bar{k}_\alpha; \omega^0)\right\} (f - \bar{k}_\alpha) < 0.$$
